I think the penny patent could also be made available in a variety of purposes in the arts and manufactures. The present system of patenting is expensive, troublesome, and often very unsatisfactory. Why not have a stamp according to value put on each article patented, to copy which, or make one like it would be, as at present, an infringement. This, however, mine and wiser heads may possibly develop; but we have ample proof that liberal terms induce support and encourage trade in the success attending the penny postal regulations, and, therefore, I think there should be a penny patent for photographers, who would be only too happy to avail themselves of its advantages.

A few words with regard to licensing photography, and I will not trespass farther on your valuable space. Mr. Swatridge recommends that photographers should be licensed, as a means of putting down some of the dens. I fear it would be only biting off our noses to spite our faces, besides doing a great deal to stop the advance of the science in the hands of amateurs, a class to whom the history of photography shows we are largely indebted. There is, however, a class of photographers who ought to contribute something to the state; but who, by the very class of their custom, do less in proportion than the established professional, who is obliged to pay rent, rates, and taxes. I mean the travelling photographer, who uses only the cheapest materials, collodion, &c., made from methylated spirit, which does not even in an indirect manner contribute to the state in the shape of duty on the spirit; neither does he use goods of foreign manufacture (must we except the miserable cheap lens) which are extensively patronised by the better class of photographers, and which pay customs duty. Rates and taxes also they pay none, and as I have witnessed lodgings are in the list sometimes. It is, therefore, only fair that they should in some way contribute towards the support of the state, as well as the established photographer, to whom they do a serious injury. The tradesman is protected by the hawker's license. The poor man who sells salt and collects old rags, bones, and metals in exchange, has to pay a license; but the returned convict who advertises "potografix on the same terms of exchange" *(fact)* pays none, yet he hawks passepartouts, cases, &c., which are not his own manufacture, as much as the other hawks salt. I think it is, therefore, only right for such photographers to pay a license of £3 a year, and if travelling with a van, £6 per van.

There would then be less frequency of the visits in the provinces of M. de Flitter from the Royal Polytechnic, or Madamoiselle Golmen, with her wonderful Photographic Museum, under the management of Herr Jeau de Puff, to cut up the trade and destroy the public confidence in photography.

I have made these suggestions, trusting they will elicit from yourself or some of your subscribers a better idea, something more practical, but at least a mode of redress for the piracy from which so many (myself among the number), suffer.—Enclosing my card, I am, dear sir, yours respectfully,

W. B. N.

SUNDAY PHOTOGRAPHY.

Dear Sir,—Will you kindly allow me to make an observation or two, in reply to your correspondent E. E. L., whose letter appeared in a recent number of the News. If it were not for the importance of the subject, and the necessity I feel that something should be done in reference to these dens, I would not have troubled you on this subject again. I agree with my friend E. E. L., when he says that the public have the matter in their hands; but unfortunately for us, as he justly remarks, the general public *are not learned in art, and are imposed upon too often at a price which a conscientious man would be glad to supply them with a genuine art photograph;* this is the rub, the public as a whole do not appreciate good photographs; but the general *cry is cheapness* and *not quality*, so we cannot, I think, expect the public to help us much in this way. I repeat that it is my opinion that a tax, if properly and judiciously carried out, would remedy the evil of which we all complain. I merely throw out this idea, leaving it to others to fill up minor details, &c., or make any alteration. I should be very sorry to see a tax, imposed in such a way that it would have the effect which your correspondent fears, of deterring any really clever and respectable man from entering the profession on account of their inability to pay for a licence. I would not propose that these licences be granted indiscriminately to any one who applies for them. It matters not if we consent to be taxed to the amount of £1, £10, £20, or £30 per annum, or what not; if the tax be ever so slight, and licences be granted to those only who possess the scientific knowledge, artistic taste, &c., requisite for the production of artistic photographs, we shall at once rid the country of these vile dens which are a disgrace both to the art and the profession, and no respectable and clever photographer would object to such a course being taken.—I remain, dear sir, yours very truly,

F. S. Swatridge.

Princes Street, Yeovil, Sept. 14, 1861.

IS PHOTOGRAPHY A FINE ART?

Sir,—I do not wish to trespass again upon your space, at any length, on this subject; but will, by your permission, just make one or two remarks in answer to those who have combatted my arguments. I am fully sensible of the courtesy and intelligence which have characterised the remarks both of yourself, and of your various correspondents, in replying to my letter, and would beg to show my appreciation of these qualities, by assuring your readers that I feel neither the jealousy of, nor contempt for, their art, that some photographers are in the habit of attributing to artists. I entertain a hearty admiration of photography, and a desire to see it estimated at its true worth.

It would be a bootless task to enter at large into all the questions raised by your correspondents; but I may remark that they all, "first-class portraitist, artist, amateur, and operator," in greater or less degree raise an issue different to that with which I dealt. I treated the subject *in esse*, they dealt with it *in posse.*

They speak of the *capabilities* of the art, I referred more especially to its hitherto achieved results. M. Claudet, in his admirable letter, refers to a period in the world's history when painting and sculpture were not regarded as fine arts. His statement is perfectly true, *neither were they at that time fine arts.* They had at that time, as you have phrased it, yet to win their spurs. Possibly photography may achieve her position in the "circle of the fine arts," ere she has seen as many years as painting and sculpture saw cycles before they were recognized; but she must *win* her position. When photographers generally have become artists, then the power they wield may be recognised as a fine art. I grant that all who cover paper or canvas with pigments are not artists; but is it necessary to affirm that the family is so large, and the ancestry so illustrious, of painters who *are* artists, that painting has established its indisputable right to a first place amongst the fine arts? Can the same be alleged of photography? Have its professors as yet established their claim indisputably? That the time will come when they may do so I will not deny. Who shall look at the infant art and limit its future? It has already proved itself an important adjunct of art. I believe it has already tended in some measure to infuse truth into painting, in place of a vicious conventionalism. But as yet it has not, by its independent productions, proved its claim to the position of a distinct fine art. I repeat it: the struggles after process, the discussions about methods, prove that something is still wanting in result.

I do not object to photographers making ambitious effort; but let them beware, as yet, of making too high claims. The universal decision of society will ultimately be just; and if photography occupy a place too lowly, it will assuredly hear the verdict, "come up higher." Let photographers then, if they can, make photography a fine art: as yet I fear they have failed, in the main, to do so.—Your obedient servant,

R. A.

Hints to Operators.

To use Buckle's Brush.—This brush which, as our readers know, consists of a tuft of clean cotton wool drawn just within a glass tube, is used for spreading solutions on plain paper. A correspondent, "D. L. J," writes to mention a method he has found very successful when using this brush. He says, "I partially fill the tube with the solution, and find it keeps the wool saturated, and consequently obviates the necessity of dipping the brush again and again."

To Graduate a Back-Ground or Sky.—During the process of strengthening or intensifying a negative, no matter what method we use, it is possible by manipulation to secure a denser deposit in parts so as to obtain gradation of tint. If it be a portrait back-ground, and a little extra light is desired behind the head, keep constantly pouring on the solution—say pyro and silver—at the part. This will be found to cause an increased deposit there, gradually softening into the surrounding parts. If the picture be a landscape, and the increased light is required in the horizon, the solution must be poured on in the same manner, but spread right along the horizon line. Care must be taken in such case to avoid burying the distance, where it is present, by over development.

Hints on Washing Prints.—Repeated changes of water are much more valuable than long soaking. In changing the water take care to drain well every drop of the water last used, and rinse before adding fresh water. A thorough draining of each print, separately, two or three times, or a separate washing with a sponge, is worth hours of soaking. Many hours soaking in the same water, especially if the prints have not been well washed previously, often seriously impoverishes prints, as they are, in that case, only remaining in a weak solution of hypo.

Photographic Fallacies.—It is an error to attribute chalkiness to overexposure; it is always the result of over-development or over-intensifying. It is an error to imagine that anything will do for a printing bath, and therefore to evaporate and use up old collodion baths. As good prints are the final aim of all efforts, the utmost care should be used to keep everything connected with printing in good order. It is an error to think that a "converted positive" will even by any process make a good negative. No matter what process be used, longer exposure is always necessary to produce a good negative, than is necessary for a good positive. It is an error to suppose a positive collodion is necessary to produce negatives by iron development. A bromo-iodized negative collodion is necessary to produce good results, and the use of an ordinary positive collodion often results in weak, grey, flat pictures. It is an error to think that spots, stains, streaks, &c. &c. are accidents, they are more generally the results of careless manipulation.

Album Portraits.—To succeed in taking these portraits, with standing figures, satisfactorily, it is important that lenses of long focus be used. Where the length of the glass-room does not admit of this, it is then desirable to have lenses made expressly for the purpose, in which the aim of the optician has been to produce a flat field. Where ordinary quarter-plate lenses are used, standing figures should be, as much as possible, avoided; the sitting figure corresponding better with the curve of the field. When the figure is standing, the camera should not be too high, and should never be tilted, otherwise the figure will appear to stand upon an inclined plain. Incongruous accessories should be avoided—such as a balustrade standing upon a carpet, or a painted back-ground with the objects lighted from the opposite direction to that in which the light falls on the figure. In mounting, the effect is best where about the eighth of an inch of white margin is left all round except at the bottom, which should have half an inch. All spots should be touched out before the picture is rolled. Rolling is almost indispensable to card portraits.

INTERNATIONAL EXHIBITION OF 1862.

Her Majesty's Commissioners have issued the following decisions:—

Medals.

"Prizes or rewards of merit, in the form of medals, will be given in Sections I., II., III."

(*a*.) These medals will be of one class, for merit, without any distinction of degree.
(*b*.) No exhibitor will receive more than one medal in any class or sub-class.
(*c*.) An International Jury will be formed for each class, and sub-class, of the Exhibition, by whom the medals will be adjudged.
(*d*.) Each Foreign Commission will be at liberty to nominate one member of the jury for each class, and sub-class, in which staple industries of their country, and its dependencies, are represented.
(*e*.) The names of the Foreign juror must be sent to Her Majesty's Commissioners before the 28th of February, 1862.
(*f*.) The British jurors will be chosen in the following manner:—
Every exhibitor will name three persons to act on the jury for each

class, or sub-class, in which he exhibits, and, from the persons so named, Her Majesty's Commissioners will select three members of the jury for each such class or sub-class.

(*g*) Her Majesty's Commissioners reserve to themselves the power of modifying these arrangements, in any particular case where it may appear to them that the strict application of the principles of these decisions would be attended with injustice.

(*h*.) The names of the jurors will be published in March, 1862.

(*i*.) The juries will be required to submit their awards, with a brief statement of the grounds of each, to Her Majesty's Commissioners, before the last day of May, 1862.

(*j*.) Should the reasons assigned for any award appear insufficient, or should no reason be given, Her Majesty's Commissioners reserve to themselves the right of confirming or rejecting it.

(*k*.) The awards will be published in the Exhibition Building, at a public ceremony, early in the month of June, 1862.

(*l*) They will immediately afterwards be conspicuously attached to the counters of the successful exhibitors, and the grounds of each award will be very briefly stated.

(*m*.) If an exhibitor accepts the office of juror, no medal can be awarded in the class, or sub-class, to which he is appointed, either to himself individually or to the firm in which he may be a partner.

(*n*.) The medals will be delivered to the exhibitors on the last day of the Exhibition.

Processes of Manufacture.

Besides making arrangements for showing machinery in motion, and illustrating it by processes, Her Majesty's Commissioners will reserve space for the exhibition of processes of manufacture, in certain handicrafts which can be carried on without danger in the building. They consider that it will be interesting to the general public to have an opportunity of seeing the following and similar processes, and will reserve sufficient space for showing one illustration of each of them :—

Steel pen making.
Pin making.
Needle making.
Button making.
Medal striking.
Gold chain making.
Engine turning for watches, &c.
Type casting.
Type printing by hand.
Lithographic printing.
Copperplate printing.
Earthenware printing.
Porcelain printing.
A potter's wheel.
Brick and drain tile making.
Glass blowing on a small scale.
Turning in metal, wood, and ivory.
Glove-making, &c.
Pillow lace making of various kinds.

Applications to exhibit these processes, with full particulars of the space required, and of any special preparation which may be necessary, should be addressed before the 1st of November, 1861, to F. R. Sandford, Esq., 454, West Strand, W.C.

Photographic Notes and Queries.

Stereo Exchange Club.

Dear Sir,—In one of your late numbers of the News, you invite the opinion of those of your readers who have had some experience in the Stereoscopic Exchange Club as at present organised, with a view to commencing it afresh under a new set of rules.

I am a member of the club, and have exchanged between one hundred and fifty and two hundred pictures, ranging in quality from very good to disgracefully bad. As a change in the rules is necessary, I do not think a better plan can be adopted than the following, a part of which was recently suggested by a correspondent, namely, that a competent umpire, yourself, for example, be selected, to whom each member must send one print from every negative he proposes for exchange, each print to be accompanied by the name of view, process, and other particulars, &c. That a list of such pictures as are considered by the umpire good enough for exchange be published in your journal with the owners' names attached. That the prints be classified under three or more heads, say A for the best, B second quality, and C third quality; none but those in the printed lists to be acknowledged by the members.

Under this arrangement such members as possess pictures A. B, or C can exchange direct with fellow-members having others of the same quality, and can at the same time express their preference for any particular subjects according to the published lists. Any cause of dissatisfaction to be laid at once before the umpire, and the prints in dispute to accompany the complaint, that he may compare them with the originals.

Allow me also to impress upon you the importance of incorporating with this, an exchange club for larger pictures, say from $6\frac{1}{2}\times4\frac{3}{4}$ to 12×10. The same arrangements for classification, &c., could be carried out and published at the same time as the stereo prints.

I am sure that a well-regulated exchange club would be very advantageous to us amateurs in more ways than one.—Your obedient servant, I. H. J.

Ebonite for Photographic Vessels.

Dear Sir,—I fully agree with your correspondent, Mr. D. J. Fitzgerald, as to the value of *ebonite* for photographic purposes; and I hasten to supply the information you desire with regard to it. The principal, and best manufacturers in England are Messrs. S. W. Silver and Co., Bishopsgate-street. Their ebonite is distinguished from other and inferior productions by being a rich, deep black, and very hard and firm, though, at the same time, very flexible.

The more common kinds are of a dirty brown colour, comparatively soft, and of uneven texture.

Ebonite is not acted upon by any heat under about 350° Fah. It will, as you correspondent states, resist all but the *strongest* acids, such as nitric, fluoric, &c.—Your obedient servant,

Leo Daft.

2, *Queen-sq., Westminster, S.W.*, 1*st October*, 1861.

Miscellaneous.

India Rubber Varnish.—That india-rubber, dissolved in various liquids makes a good varnish, is well-known, but in general they are too viscid for general purposes, and are only good for making stuffs waterproof. India-rubber liquified by heat, dissolved in oil of coal-tar, or drying linseed oil, does not give a varnish of sufficient fluency, or free from smell; moreover, a considerable quantity of india-rubber remains undissolved in a gelatinous state, suspended in the liquid, so that the solution is never clear. Dr. Bolly has recently published some remarks on the subject, which may be useful. If india-rubber be cut into small pieces and digested in sulphuret of carbon, a jelly will be formed; this must be treated with benzine, by which means a transparent, but still yellowish liquid will be obtained. A more colourless solution may be prepared by digesting india-rubber cut into small pieces for many days in benzine, and frequently shaking the bottle which contains it. The jelly thus formed will partly dissolve, yielding a liquid which is thicker than benzine, and may be obtained very clear by filtration and rest. The residue may be separated by straining, and will form an excellent waterproof composition. As for the liquid itself it incorporates easily with all fixed or volatile oils. It dries very fast, and does not shine, unlesss mixed with resinous varnishes. It is extremely flexible, may be spread in very thin layers, and remians unaltered under the influence of light and air. It may be employed to varnish maps or prints, because it does not effect the whiteness of the paper, does not reflect light disagreeably as resinous varnishes do, and is not subject to crack or come off in scales. It may be used to fix black chalk, or pencil drawings; and unsized paper, when covered with this varnish may be written with ink.—*Galignani.*

Domesday Book.—The *Times* says:—"The publication of the part of the "Domosday Book" relating to Cornwall has now been before the public some time, and, as is stated in the introductory remarks to this volume, the prosecution of the publication, county by county, must depend more upon the wishes of the public than upon the Government. The publication of the part relating to Cornwall was permitted by the Government as an experiment to test the value of photozincography for producing fac-similes of our ancient records, and was entrusted to Colonel Sir Henry James, the Director of the Ordnance Survey, the original being of such inestimable value that it could not be allowed to pass into the hands of any private person, even supposing any private person was capable of copying it by this new art. The art of photozincography has, in the hands of the officers of the Ordnance Survey, been greatly improved since the publication of the pert of Domesday relating to Cornwall. And perfect as this copy appears to be, and in reality is, still, by slight modifications in the details of the process. The copies now produced have a sharpness and clearness in the outline not before attained.

Talk in the Studio.

Lectureship of Photography at King's College.—Mr. Sutton has resigned the office of lecturer on photography at King's College. An invincible repugnance to life in London, and an unconquerable longing for the wild solitude of St. Brelade's are, he informs us, the reasons for taking this step. Dr. Diamond, it is rumoured, will succeed him in the office.

British Association at Manchester.—It has been the subject of general remark amongst those interested in the proceedings of the British Association for the Advancement of Science, that on no former occasion has the reports in the local press been so copious or correct as on this occasion. It may gratify some of our readers to know that they may procure a very excellent and full account of all the proceedings, with the most interesting sectional papers in full, and others in abstract, in a pamphlet just published at the office of the *Manchester Guardian*, being a reprint of the reports from that paper.

Photography in the Exhibition.—The *Daily Telegraph*, in an article, a few days ago, on the Exhibition, had the following:—"We published last week an extraordinary decision of the authorities with regard to the exhibition of photographs—that decision, we are now told, has been rescinded. The statement we put forth, on good authority, was that photographic specimens, not coming properly within the limits of artistic description, would be classed with machinery. Our great operators were reasonably dissatisfied with this arrangement. Whatever the objection to their taking rank with the followers of pictorial art, it is certainly an anomalous proceeding to put them among machinists. The course taken has been a compromise. Photography is treated as it would have been in the old unscientific days, when a true classification was often inconvenient, if not impossible. It is placed, that is to say, in a corner apart, as a 'nondescript' object of exhibition." The "rescinding" referred to, simply means, we presume, the decision already known to our readers; namely, that photography will have a separate department.

Photographic Commercial Success.—It has been the custom of late of some people to speak of the palmy commercial days of photography as belonging to the past. From some recent statements which have come to our ears, there never was a period when such large incomes were realized by able and enterprizing professional photographers. One Parisian portraitist, we are assured, is at the present moment taking not less than £48,000 a-year. Whether any photographer in England is doing an equally large business we cannot say, but should be inclined to doubt. We have heard of one, however, in the metropolis, whose receipts are £12,000 a-year; and of another in the provinces whose business amounts to £10,000 a-year. If these be facts, the palmy days of photography are certainly not gone.

South London Photographic Society.—The members of this society are reminded that the first meeting, after the summer recess, will be held in St. Peter's School Room, on the evening of next Thursday, October 10th; when a paper on "The Photographer's Model" will be read by Mr. Wall.

To Correspondents.

A. B. C.—Prints should always be fixed before toning for several reasons; the most cogent of which, it is a very difficult and slow process to tone them after fixing. They should be toned in yellow light; but you may have plenty of it, and, if need be, you may give a hasty glance to judge of their progress by diffused day-light, without much risk, if you are careful. The bromo-iodized collodion you name is very good; it is better not quite freshly iodized. Use citric acid in your intensifying solution of pyro and silver; it will render the risk of fogging less. You may obtain a pretty good French quarter-plate lens for 30s.; but it will not cover standing figures in card portraits properly.

Positive.—There are several methods of converting positives into negatives; but unless the positive has been over-exposed it will not make a good negative. First, pour over the picture a solution consisting of iodine one grain, iodide of potassium one grain, water one ounce. In a few minutes wash well, and develop with the ordinary solution of pyrogallic acid, with a few drops of silver. 2. Card portraits are usually taken on quarter-plates, for which, of course, carriers are made. If your lens produce good pictures, 5 by 5, there is no reason why it should not produce good card portraits.

A Constant Reader.—The partial dissolving of your picture in varnishing arises from the varnish being made of too highly rectified alcohol. A "crystal" varnish, of which the solvent is benzole, not alcohol, will prevent the occurrence, and answer perfectly well for positives.

T. A. R.—A virulent case of "measles." Your prints are imperfectly fixed. The hypo is too weak, or has been too long in use, or the prints have been stuck together and imperfectly immersed. This has caused the formation of insoluble hyposulphite of silver, which on seeing the light decomposes, and produces the deplorable result your prints present. Use fresh hypo, of a strength of not less than one ounce of hypo in five of water; and see that the prints are well immersed and kept moving. The negatives we presume are instantaneous.

J. G. L.—We can only account for the non-arrival of several letters recently by attributing it to the growing dishonesty of post-office servants. Regarding the London Photographic Society we regret to say we cannot give you much help. Possibly the secretary was from home when you wrote. Regarding the journal, possibly you may get redress by writing to the publishers, Messrs. Taylor and Francis; that method we know is irregular, but it may possibly serve your purpose. The Sœhnée varnish is not spoilt for negatives by becoming coloured. We are not familiar with the second spirit varnish you name; but if it is not so hard as the Sœhnée, it is not so good for negatives. The third varnish mentioned is good, but not better than Sœhnée. The use of a very small central stop will, under some circumstances, cause a spot of light in the middle of the picture with any double combination of lenses. The remedy is to avoid the use of a stop too small; or, use a hood of some kind in front of the lens to shade off direct light not coming from the objects to be taken. This will generally answer. There are various arrangements for uncovering the lens for instantaneous exposures, and we cannot undertake to say which is best. Perhaps nothing surpasses the focussing cloth, or a hat or a cap. We have used all these successfully. The addition of acetic acid to a bath prepared with common water as recommended by Mr. Fry, would neutralize the results to be obtained. If you make another bath on the same principle, avoid the addition of acetic acid. If you adopt the plan recommended by Mr. Sellers, careful decanting may serve instead of filtering. Of the collodion named the two first are best. Regarding the new instrument of which you speak, probably mathematical instrument makers would be more likely to undertake it than opticians.

J. H. J.—We do not know the address of M. Bertsch; but probably a letter addressed to him at the French society would find him. The address of the society is No. 11, Rue Drouot, Paris. The address of Messrs. Bernstingl and Co. is Coleman Street, City.

J. Collins.—We should prefer the first of the names you mention; but you cannot ensure quick action, flat field, and defining powers "well up to the corners" in a cheap lens. It is to secure these qualities that the higher prices are paid to first-class English makers. We have used very respectable cheap French lenses, but we have rarely found them cover well the size for which they were sold. The best plan is to write to such a dealer as the first named, and ask him to *select* you one, even if you pay extra for the selection.

Braisheeth Avoia.—The reason your silver bath removes the albumen is that it is too weak, or that it is alkaline. Make your bath 70 grains to the ounce to begin with, and keep up the strength from time to time. If it very rapidly discolours add a few drops of nitric acid. When it gets very dark, agitate with kaolin and filter. There is no need at any time to throw it away. Always float albumenized paper; do not brush it. The fact that your paper darkened slowly under the action of light proves that the silver solution was nearly exhausted. To secure freedom from milkiness after using kaolin, always adopt the plan of letting it stand some hours after filtration, and then decant carefully, not to disturb the slight sediment which may remain. The various photographic papers are to be had of dealers in photographic materials. You will frequently find announcements in the advertisement pages of the Photographic News as regards price, &c. Common writing or printing papers are rarely good substitutes for photographic papers.

G. Smith.—Either the use of iodine followed by pyro and silver, or bichloride of mercury, followed by iodide of potassium, ought to answer for intensifying Fothergill negatives. In the latter case, use the solutions very weak. Thank you for the hints in your letter, which shall be used.

Caxton.—If you had accurately followed the instructions, you could not have failed to get a picture. State exactly what you have done, in detail, and we may be able to point out the source of error.

G. M.—The cause of the measly effect of the prints is undoubtedly imperfect fixation. If they be, as you state, the only two out of a large batch that are so affected, they have probably been amongst the last fixed in the same hypo, which was getting exhausted, and probably these prints were stuck together, or not properly submerged to allow the solution free access to them. See answer to T. A. R.

Sewad.—If a print be too pale there are no means of darkening it. 2. An iron developer for negatives may be made thus: protosulphate of iron 15 grains, glacial acetic acid 15 minims, water 1 ounce, alcohol *quantum suff.* 3. We cannot undertake to say which is the best varnish for positives.

Narberth.—The formulæ for the portrait lens of the various makers you name, have not been published, nor could we afford space for them here. To give any satisfactory answer to your questions, would require a treatise on optics. The rule for determining the proper distance between the lenses of a portrait combination, varies with the foci of the lenses. When their respective foci are as two or three the distance may be about one-third of the equivalent focus of the combination.

J. S.—The varnish referred to is advertised in our columns as sold by Mr. Rigge, of Bond-street. We do not know of a varnish for card portraits. Rolling is better than varnishing.

A. B. C.—A negative developed with iron may be further intensified with pyro and silver, or bichloride of mercury, followed by iodide or ammonia.

Tannin.—There is no method of removing the marks you describe but careful touching out. In developing, let your pyro run freely over the plate, and cover it well before adding any silver, and you will avoid such stains. You do not state the size of the lens to which you refer. We do not know much about the quality of that maker's lenses generally; but in his catalogue we find the 10 by 8 marked £5.

C. E. L.—We do not like the system of re-dipping plates into the nitrate bath before development. It is dangerous to the bath, and often causes fogging in the plate. If necessary, flooding the plate with a dilute and acid silver solution is better. M. Gaudin is an ingenious experimentalist, but not always a safe guide. His statements must be taken *cum grano salis*. A little more acid is generally the remedy for a bath which produces streaks. We have always found that answer. Using older and more coloured collodion or adding a little tincture of iodine, serves the same purpose. Oxide of silver is insoluble in water, but is held in mechanical suspension on shaking in a bottle of water. A few drops of this turbid solution is generally sufficient for a pint of nitrate bath.

"Phos" and "Z. Y."—Letters for both lie at our office.

An Amateur.—A whole plate lens will answer perfectly for card portraits if your room be long enough. The only difficulty will be in dull or thick weather, when the long distance between the sitter and the camera will interpose a great deal of partially opaque atmosphere, to dim the brilliancy of the image.

H. Newman and some other correspondents in our next.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 162.—*October* 11, 1861.

SUNDAY PHOTOGRAPHY.

We have pleasure in being able to state that the agitation we recently initiated regarding this disgrace to the art and profession is likely to bear substantial fruit. An organization for the purpose of securing the entire suppresion of a practice which has grown into a public nuisance, is now on foot, and will, we hope, very soon be in successful operation. We hope to be able to announce full particulars very shortly.

We have received several letters on this subject, and others arising out of its consideration, which arrived too late for attention in the present number.

RAPID PHOTOGRAPHY.

We have recently had our attention called to the singular disparity between the ideas of rapid photography, and to the coincident practice, which exist in this country and in France. With a few unimportant exceptions instantaneous photographs were, until very recently, comparatively rare in France. The recent production, by Messrs. Ferrier and Soulier, of a series of instantaneous street views in Paris, was a circumstance so novel as to call forth an unwonted amount of excitement and attention, so that it was deemed necessary to account for the unprecedented sensitiveness by referring to some extraordinary condition of the silver bath, and a number of the photographic *gobemouches* were forthwith engaged in spoiling their baths by the addition of formic acid. Yet long before this an enterprising English firm had produced excellent instantaneous pictures of the same scenes. Not only so, for with the clear atmosphere and fine light of Paris this was, comparatively, speaking an easy task; but street views of London, of Edinburgh, and other of our smoky and fog-visited cities, as well as of river and sea views with moving shipping, were common in this country; several of our professional photographers having secured a reputation for instantaneous work, and many of our amateurs having worked successfully in the same direction.

We were, notwithstanding this, not a little surprised the other day in learning from a professional photographer, who had recently had an opportunity of visiting some of the Parisian ateliers, the long sittings usually given, and deemed necessary, in portraiture. In this country the time of sitting for card-portraits in summer weather, and with a good light, averages, so far as we have opportunity of ascertaining, from two to ten seconds, varying with the kind of lens and the lighting facilities possessed in different establishments. We have asked first-class operators, both in London and the provinces, and have been informed that four or five seconds was an average sitting, whilst, on occasion, for children, a much shorter exposure was given. Our own experience is confirmatory of the statements. In Paris, we are informed, thirty or thirty five seconds is the usual time of exposure on a bright summer day! One of the French operators, on being informed of the short exposure common in England, replied, with a shrug, that the pictures must be very hard.

We cannot pretend to account for this. The French portraits are certainly not hard; they are very fine, soft, and delicate: but we are unwilling to admit that they are better than the best English pictures, taken with much shorter exposure. Something is doubtless due to their lenses. The best French lenses are not, in our opinion, at all equal to those of the best English makers; and the fact that the lenses with which Messrs. Ferrier produced their instantaneous views were procured from one of our first English opticians bears out this opinion. We learn, moreover, that it is customary in Paris to take card portraits with lenses of very long focus. Instead of attempting, as some of our portraitists foolishly do, to take them with a quarter-plate lens, they use a lens of a focus somewhat longer than the usual half-plate portrait lens. But this is insufficient to account for the enormous disparity in the time of exposure.

Again, one of their authorities has recently insisted, with considerable emphasis, on the importance of using the collodion and nitrate bath acid, and the iron developing solution stale, in order to get clean negatives. If this be the usual practice, it will help to account somewhat for the fact in question. With some of their operators, we believe, it is the practice to permit a few minutes to elapse between coating the plate and immersing it in the bath, so as to allow it to be set firm all over before it comes into contact with the silver solution. This, as most experienced photographers are aware, tends to diminish the sensibility of the film.

Whatever the cause, or combination of causes, we are assured of the fact, that whilst working with bromo-iodized collodion and iron development, the same as the majority of English portraitists, they are in the habit of giving an exposure in the fine light of Paris three or four times as long as is customary in this country.

As associated somewhat with this question of rapidity, we may here make one or two remarks on an article in a French contemporary, who is outraged by the statement which appeared in our pages some months ago, to the effect that Mr. Breese, of Birmingham, had exhibited some stereographs, said to be produced by the light of the moon. Our article reviewing these pictures was translated into the *Bulletin* of the French Society, and M. Mc A. Gaudin, in *La Lumière*, feels himself constrained to expose this "mystification," in which he considers that "the credulity of the writers equals the audacity of the photographer" who produced the pictures. "According to me," M. Gaudin says further, "these images are the results of feeble instantaneous negatives, obtained in full sunlight; and it is their feebleness which produces the illusion of moonlight." He adds that on reading the account on its first appearance, he regarded it as "un puff a l'addresse de riches lords anglais!" Mr. Breese will, doubtless be as much amused as ourselves at the unexpected manner in which he receives his patent of nobility.

But badinage apart, M. Gaudin should be somewhat careful how he suggests the use of the term audacity. Mr. Breese makes a statement, which if M. Gaudin cannot understand, he cannot, at least, disprove. The most which he can, with any propriety, say is, that he himself is not aware of any process sufficiently sensitive to yield impressions by the light of the moon. To this Mr. Breese replies, "Very good; but I do: and my process is a secret." M. Gaudin has set the example in this respect. He has recently, in common with several other persons, discovered a method of uniting in one compound which he calls "photogene," the sensitive salts of silver. So long as the preparation was a comparative failure, he published the details; but on attaining something like success, he announced, not the particulars, but that he would manufacture it for sale. We do not complain of this; we merely point out the analogy of his position, to a considerable extent, with that of Mr. Breese.

Regarding our own "credulity" in the matter, we might content ourselves to smile at the charge. We might add that we had never once expressed an opinion, either way, as to the mode in which the pictures were produced; we simply described the results, and stated that we had Mr. Breese's assurance that they were genuine moonlight pictures, without any trick. But we do not hesitate to go further, and affirm that the pictures themselves bear the strongest possibly evidence to the truth of their claims. They are altogether unlike the results of the small artifice to which M. Gaudin refers, and which, if we remember rightly, was initiated be one of his countrymen. The substitution of weak sunlight pictures, for moonlight effects, is generally easily detected.

In some of these pictures,—one for instance, the moon in the midst of a mass of cumulus clouds—the effect is unmistakeable. Nor does it appear to us a subject beyond the powers of the ordinary collodion process in its most sensitive condition. The moon can be taken, we know well, and we see no reason why the silver edges of the clouds which it brilliantly illuminates should not also be produced. But it is not necessary to argue the case thus. Mr. Breese says, "I have a secret process of unprecedented sensitiveness." Does it need very great stretch of credulity to believe this, and the more so when some exquisite specimens are presented as vouchers?

The whole history of photography has been one constant demand upon such credulity. Each step in its further advancement may be marked by extraordinary demands upon our faith, such as the discovery of unexpected phenomena, or results opposed to or transcending former experience must ever bring. The photographic journalist is doubtless bound to protect his readers from the impositions of boasting charlatans; but he should beware, in speaking of facts with which he has no familiarity, of coupling the terms "audacity" with the experimentalist and "credulity" with the recorder.

PHOTOGRAPHY IN AMERICA.

We recently had an opportunity of conversing with a gentleman who had just returned to this country from the United States, where he had been for some time engaged as a professional photographer. Presuming that some account of what we learnt regarding the practice of photography amongst our Yankee cousins, who are generally considered successful photographers, will be as interesting to our readers as the gossip we had on the subject was to us, we proceed briefly to record the substance of the conversation.

Knowing that the production of glass positives had been practised to a much larger extent, and with greater success in the States, than in this country, we asked some questions regarding their mode of manipulation, &c.

"I believe that the collodion positives, or ambrotypes, for they are always so called, produced in the States are the finest in the world. Some of them possessing very great beauty; brilliant, delicate, and vigorous." Until very recently the ambrotype process was very largely practised; but .is now becoming superseded by the *carte de visite* portrait, the rage for which equalled that on this side of the Atlantic.

"The source of their success in producing ambrotypes," he added, "I can only attribute to the fine light and exquisitely pure atmosphere of the States. The chief peculiarities of their formulæ and mode of manipulating consist in the use of a strong nitrate bath, not less than forty-five grains of silver to the ounce being common; and a highly iodized and bromidized collodion, five or six grains of iodide to the ounce being the usual proportion. They do not generally use nitric acid either in the bath or developer, acetic acid being added to both. The pictures are usually finished without any colour, but a very slight amount of tinting highly coloured ambrotypes not being in request."

We may here explain the meaning and origin of the term ambrotype, which are not usually known in this country. The word was first applied by Mr. Cutting, of Boston, and is thus explained in the specification of a patent in which he claimed the use of bromides in collodion, "by the use of the said process"—the ordinary process now used for producing glass positives—"the beauty and permanency of such pictures are greatly increased, and I have on this account, styled the process 'ambrotype,' from the Greek word αμβροτος, immortal."

"A short time ago," remarked our friend from the States, "there was quite a *furore* for Funnygraphs," as they styled a certain class of caricatures, in which a large head is appended to a grotesque, small body. The head is usually a genuine photographic portrait, to which the diminutive body is added by means of the pencil. A negative is then produced from the print treated in this manner, and printed in the usual card portrait size for sale. We have one before us at this moment of Dr. Kane, the celebrated arctic explorer, by Meade, Brothers. Some of our readers may have seen that an effort was made to introduce a similar style of portraits in this country. The attempt was, fortunately, not successful. We regard the wanton travesty of the portrait of a great man, as about on a par with a burlesque of one of Shakespeare's plays, a production which at its funniest shows a lamentable poverty of invention, and lack of an appreciative and venerating spirit.

The use of iron for developing negatives is universal amongst American operators; various methods of intensifying being adopted when further vigor is required. One method which is very common amongst them, is that we have heard described as often practised by Mr. Wilson of Aberdeen. After the picture is fully developed by the first application of iron, it is well washed, and examined to ascertain if it be sufficiently vigorous for printing purposes. If it be too thin, a little of the silver solution from the bath is poured over the plate, which is then again treated with the iron developer; this process being repeated until sufficient density is obtained. Some of the American operators improve the printing qualities of their iron negatives by the application of hydrosulphate of ammonia, which changes the colour of the deposit from grey to brown, and renders them less permeable to actinic light. Others use bi-chloride of mercury with subsequent darkening solutions: but the pyrogallic acid development is all but abandoned.

Until very recently plain paper was universally used for printing purposes, the reason assigned by our friend being the inability of the American operators to tone albumenized paper. This will be better understood by our readers when we explain that the sel d'or toning process, so unsuited to albumenized prints, was that in general use amongst them. Recently, however, the use of albumenized paper has become more general, and a method has there been adopted with success, which has generally, in this country, been thought inapplicable to albumenized paper, we refer to the ammonia-nitrate process. The usual ammonia-nitrate bath, as experienced photographers are aware, has a tendency to dissolve the albumen from the paper: this tendency has frustrated any attempt to make it available except for plain paper. In preparing the ammonia-nitrate bath for albumenized paper, the American photographers make it considerably stronger than usual, and then add to it a little ether, about one part in sixteen of the solution. The bath so prepared, we are informed, does not dissolve the albumen. If so, we are disposed to attribute it rather to the extra strength of the silver solution than to the presence of ether, which we are inclined to believe would have no effect whatever on the film of dried albumen.

The advantages of the ammonia-nitrate process for albumenized paper are said to be superior depth and richness of tone, and greater sensitiveness. The latter we can readily believe, and the former we are assured is the fact; we have not, however, seen any of the specimens so produced.

The practice of enlarging is, we understand, coming into considerable use in the States, three-quarter figures, life-size, being a favourite style. Woodward's camera is generally used as the means of enlarging; other cameras for the same purpose, announced from time to time as improvements, not having come into much notice.

One of the especially distinguishing features of American photographic establishments, to which our friend refers, is the colossal character of their glass-rooms as compared with those in this country. The glass-room of first-class American establishments usually covers the whole of a very large building, are proportionately lofty, and are surmounted with what they term "mammoth skylights." These large rooms, together with the clear dry atmosphere and fine light, afford unusual facilities for the production of brilliant photographs.

Amateur photographers there are, comparatively speaking, none, and except for the production of stereoscopic pictures, landscape photography is little known or practised.

THE PHOTOGRAPHIC CONTRACT AND THE INTERNATIONAL EXHIBITION.

In a recent issue of the *Times*, the following letter appeared, dated from the offices of the International Exhibition, and signed by F. R. Sandford, the Secretary to Her Majesty's Commissioners.

"The attention of Her Majesty's Commissioners for the Exhibition of 1862, has been drawn to certain erroneous statements which have appeared in the public press, with respect to the contract which they have entered into with Messrs. Birnstingl and Co. I am directed to request that you will have the goodness to make known, through your columns, that this contract refers only to photographing the building during the period of its erection; that it will expire on the 12th of February, 1862, the day on which articles will be first received into the Exhibition; and that in any subsequent arrangement which they may make, Her Majesty's Commissioners will certainly not grant permission to any one to take photographs, or drawings of any work of industry or art which may be intrusted to their care, without the express permission of the exhibitors."

Various rumours have been afloat as to the nature and terms of the contract for photographing the progress of the building. A photographic contemporary announced that the terms of the contract which was accepted, were simply an unconditional offer to double the amount of any other tender. The paragraph to which the letter of Mr. Sandford more especially refers, is, we believe, the following, which appeared in some of the minor prints:—

"A firm in the City, it is said, has secured the right to photograph everything exhibited in the Exhibition, and has, of course, paid handsomely for the right. Tenders were invited, and the firm alluded to offered £7,000, which is double the amount of any other tender."

One part of the statement receives a substantial contradiction in the letter of Mr. Sandford, and as regards the terms of the contract, we have the best authority for stating that all the rumours and statements which have received currency are purely conjectural, and have but little foundation in fact. Regarding the amount of the tender above referred to, the statement is altogether wild and absurd, the sum paid probably not reaching in hundreds the amount stated in thousands. The number of tenders forwarded to Her Majesty's Commissioners was not large, and some of the offers indicated an amusingly small estimate of the advantages to be gained by the privilege of photographing during the time included in the contract. One eminent photographer illustrated his conception of the worth of such an opportunity, by offering as an equivalent, to guarantee to the Commissioners one print from each negative which should be produced under the contract. An eminent West End photographic firm offered a sum of £50 for the privilege; and another, an extensive City photographic house, offered, we understand, £100. This latter sum was, we believe, one of the highest offers. The actual amount paid, and the terms of the contract have not, as we have said, transpired, as we were recently assured by the contractor, that it was a matter solely known to himself and the Commissioners.

The firm with whom the contract was made is that of L. Birnstingl and Co., foreign merchants. The bulk of the photography is executed, we believe, for the contractors, by Messrs. Cundall and Downes, by whom some very fine views of the progress of the building have been already produced. The matter will, again, before the opening of the building, be offered to public tender amongst photographers, and the next contract will necessarily be of a much more extensive character than that at present existing. Those interested will doubtless keep the subject under attention.

EQUESTRIAN PORTRAITS.

Amongst the novelties to which attention has recently been directed, and which will probably come into more extensive demand, are equestrian portraits. We have at the present moment some before us which are very fine, both in whole-plate and card size. It is important to be careful in the selection of background and of position. It is not desirable to fill the plate with the figure; but to include such adjuncts as will make a picture of the whole. The nature of the background and accessories is, therefore, important. A flat piece of country, with the figure of horse and rider cutting against the sky would be very uninteresting. The end of a house, or a high blank wall, would be even worse. A varied landscape having any extreme distance would be unsuitable, because the full aperture, or nearly so, of a portrait lens would frequently be necessary, on the score of rapidity, and much depth of definition, for the distant parts of the landscape, could scarcely be hoped for. A background consisting of sufficiently varied lines to make a satisfactory composition, whilst it furnishes sufficient relief to the figures, should be aimed at. It often happens that there is not much choice available; but we throw out these hints to suggest the importance of making the best of what there is, as we have seen some such pictures in which apparently the subject had received no attention whatever.

In one fine picture before us, the background is very good: the horse, a fine Arab, has just been brought round to the front of the mansion, and is held by the groom. The background consists of the portico with its Tuscan columns, a conservatory, and varied kinds of foliage. In another the same horse is mounted by a lady, the background consisting of the same objects from a fresh point of view. In another picture is a rustic stone wall, above which tower some fine trees, through the branches of which the sky is seen, together forming an appropriate background.

As regards position, although it is not always possible to pose a horse, a good deal may be done by leading it forward a step or two until the feet rest in a satisfactory position, giving the effect of a proper balance of the figure. It is quite possible by inattention in this respect to get a view in which the animal shall appear to have only two legs. We saw a picture the other day, which from the position, and from imperfect definition, gave the effect of having one hind-leg with two feet growing from it, only a small portion of the further hind-leg, consisting of the hock and hoof, projecting before the other.

A spirited position of the head, and perfect quietness for a few seconds, are obtained by a method regarded as an important secret, we believe, by some of the artists in France who are largely engaged in producing equestrian portraits. It consists in giving a shrill whistle the moment before exposure. Immediately the attention is arrested, the head is turned, the eyes brighten, the ears prick up, and a few seconds of perfect quiescence, in a most spirited and desirable position, are obtained, in which to secure and perpetuate the finest expression of the noble model.

Few subjects make more pleasing pictures, and we commend the further prosecution of this branch of photography as one in which profit and credit are to be obtained by portraitists.

INSTANTANEOUS MINIATURE PORTRAITS OR PISTOLGRAMS.

There are few of our readers who will be likely to fall into the error of *Punch's* correspondent, who wrote in a state of extreme nervous apprehension, to enquire what were the unknown horrors which lurked in the "Pistolgrams of Babies," which she saw daily advertised in the *Times*, and one of which she was in constant apprehension that some inconsiderate friend might be presenting to her darling. The term "pistolgram," as most of our readers know, is the name given by Mr. Skaife to the productions of his miniature camera, which from its size, shape, rapidity, and trigger shutter, he has given the somewhat uneuphonious and incongruous name of pistolgraph.

To those of our readers not already familiar with the subject, a description of the instrument and of the mode of working with it as detailed in the "Guide to the Pistolgraph," by Mr. Skaife, a new edition of which is just published, will be interesting.

Mr. Skaife sets out with a declared distaste for the cumbrous machinery of ordinary photography, and for the absence of rapidity which generally characterizes their operations. He manifestly possesses, moreover, a decided love for the minute size of the "photo-gems," the production of his pocket apparatus, and without intimating that the value of a picture increases in the inverse ratio of its size, he regards size at least as a small element in value, and apropos of this subject relates the following anecdote:—

"A Swiss peasant went one day into a watchmaker's shop in Geneva to buy a watch, and after higgling a considerable time over the price of a large old turnip-shaped timepiece, value some twenty francs, at last, by way of finish to the bargain exclaimed, *à moins, Monsieur, vous me donnerez cette petite bagatelle audessus du marché.*"* The little bagatelle was a miniature jewelled watch worth one hundred guineas."

Many of our readers are aware that it is a favourite theory with Sir David Brewster that pictures taken with large lenses are absolutely untrue to nature, as consisting of a series of dissimilar images, produced by different parts of the lens, superposed upon each other. As might be anticipated, therefore, we have his authority to the effect that the photographs produced by the pistol camera are "far more truthful and correct than those taken by the ordinary camera." Without endorsing this opinion, we have no hesitation in assuring those of our readers who have not seen "pistolgrams," that many of them really are gems of positive portraiture; and from their absolutely instantaneous character afford the facility for catching the natural unstudied expression which lends such a charm to a likeness.

The pistol camera is made entirely of metal; brass, we believe, being generally used. Its greatest dimensions do not exceed about three inches. The body of the camera consists of three tubes, the largest little more than an inch diameter, sliding within each other like a telescope. The back, into which the body screws, is large enough to take a plate a little more than two inches long by one inch wide.

It is to the character of the lenses, of course, the extreme rapidity of the pistol camera is due. These are manufactured by Mr. Dallmeyer, and consist of a portrait combination of very short focus and wide aperture. The diameter of the lenses is seven-eighths of a inch, and the aperture generally used for moving objects five-eighths of an inch. The equivalent focus of the combination is, we believe, about an inch, or little more. It will readily seem that the relation of aperture to focus, upon which rapidity depends, is widely different to that usually existing in portrait combinations. In few lenses is the full aperture greater than one-fourth of the length of focus; that is, the proportion frequently found in portrait combinations. In Mr. Skaife's lens we find the full aperture nearly equal to the focal length, and the aperture commonly used at least equal to half the focal length. Here is the source of rapidity which gives unequalled facilities for securing moving objects with shortest possible amount of exposure.

To secure the full value of the rapid action of the lenses, an equally rapid means of uncovering and covering the lens is important. To effect this, a spring shutter, which is patented, is used. This shutter is kept closed by a spring, which may be released for a momentary exposure by means of a trigger, or kept open for a longer period by detatching the trigger and releasing the spring by the pressure of the finger for the time required.

In working with such small plates, as may readily be conceived, it would be very inconvenient to manipulate them in the usual manner. The size of the plate required rarely exceeds one inch square: for convenience, however, the plate is used just twice the length, one half being used entirely for the purpose of holding it. The amount of solution kept in the bath is just sufficient to cover one inch, and the plate is placed in the solution without a dipper, and withdrawn by taking hold of the superfluous glass. In Mr. Skaife's practice all the manipulations, exciting, developing, and fixing, are performed by dipping.

For out-door operations with the pistolgraph, Mr. Skaife has devised a waterproof bag which can be distended into rigidity by inflating certain air-tubes. This bag, which is about the size of a lady's muff, contains the whole equipment necessary for operating. The whole of the manipulations are managed by the sensation of touch, and calculation of time; sight being, for the occasion, dispensed with. The bag contains three small glass jars, one of which contains the nitrate solution, a second the iron developer, and a third a solution of salt and water For these operations each plate has a small piece of glass cemented on to the end by which it is to be handled, by touching which the position of the unseen plate is *felt*, in order to keep it in its right place in each stage. For all objects beyond a distance of about twenty-five feet the pistolgraph requires no focussing, everything beyond that distance to infinity appearing in equal focus. The excited plate being, therefore, placed in the back of the camera, in the dark bag, the instrument is withdrawn and "fired" at any view within range. It is now returned to the bag, developed by immersion in the iron bath, next plunged into the bath of salt and water, and may then be safely examined in white light. It is kept in the bath of salt water until opportunity is found at home for fixing it: the cemented piece of glass allows several plates to be placed in the salt bath without injuring each other. Those whose fancy inclines them to the tiny and minute have thus a photographic equipment reduced to something little more than a waistcoat-pocket affair; and they can, if they choose, enlarge their results at home at leisure, or have them enlarged by means of the solar camera.

Mr. Skaife devotes himself chiefly to the production of "pistolgram" portraits for "chromo-crystals." These chromo-crystals consists of a small glass positive cemented on to a piece of purple or other glass, and afterwards cut into form by the lapidary. The mode of cementing is something similar to that patented some years ago by Mr. Cutting, under the title of "balsam-sealing." Mr. Skaife thus describes the operation of cementing:

"Pistolgram cement is prepared by first filtering Canadian balsam through a piece of fine lawn or muslin, then evaporating it over the flame of a lamp, until the balsam has attained the consistence of amber (when cold). When a pistolgram is required for jewellery purposes, a fragment of the hardened balsam is chipped from the solid and placed upon a piece of dark coloured glass, with which it is intended to back the miniature picture. Then the glass with its superposed amber-like fragment, is held over a lamp until the fragment melts. This done, the pistolgram, previously well heated, is next placed (film side), in contact with the melted fragment, and gently pressed thereupon, until the latter is extended all over between the back and front plates inner surfaces, and its superfluity expelled at the sides, along with all objectionable air bubbles; which done, the compound, when cold, will be found sufficiently

* At least, sir, you will give me this little trifle into the bargain.

homogeneous to admit of being cut to the required shape with a diamond, and finally polished on the lapidary's mill like any other piece of solid glass or stone."

To those who have opportunity, a visit to Mr. Skaife's studio will be found very interesting, an examination of the exquisitely delicate little portraits and park and street scenes well repaying an inspection.

NEW INSTANTANEOUS CAMERA.

Mr. Sutton has recently patented a new form of instantaneous camera. In it the excited collodion plate is placed and uncovered before focussing. The focussing glass is fitted into an aperture at the top of the camera, and therefore at right angles with the collodion plate. Between the two is placed a mirror fixed at an angle of 45°, which arrests the rays coming to a focus on the collodion plate, and throws them up on to the ground glass, which is of course placed at the same angle with regard to the mirror, as the sensitive plate. Whilst the mirror is in this position it protects the sensitive plate from light, and when the focussing is completed, and the subject is ready for exposure, the mirror is turned up out of the way by means of a handle outside, so that the image at once falls on the sensitive plate. The idea possesses much ingenuity, and should no practical difficulty intervene, will doubless come into use for some purposes if its inventor do not create suspicion of its worth by heralding with injudicious praise. We subjoin the following extract from the "Notes," describing some of its features.

"Within the camera there is placed a moveable reflector, making an angle of 45° with the bottom, and which can be turned up and down with pleasure, by means of an external handle, exactly in the same way as Mr. Dallmeyer's instantaneous shutter. The ground glass is placed horizontally in the top of the camera, and when the reflector is down, the image is thrown upon the ground glass *erect* (but reversed as regards right and left),—and this image can be accurately focussed upon the horizontal ground glass by turning the focussing screw of the lens,—and when in focus upon the ground glass it is also in perfect focus upon the collodion film, which is symmetrically situated on the other side of the reflector, and in its usual place in the camera. Thus, when the reflector is down, a pencil converging to a point P upon the collodion film is arrested in its course, and reflected upwards to a point p upon the ground glass,—the points P and p being symmetrically situated with respect to the reflector.* It is hardly necessary to observe, that in order to obtain a correct focus upon both the ground glass and the collodion film, the three planes of the film, the mercurialized side of the reflector, and the ground side of the focussing glass, must all have a common line of intersection;—a condition which can be insured in a well made camera without any practical difficulty, because in making the camera, the ground glass can be accurately fixed in the rebate of the frame after the reflector and dark slide have been fitted in their place.

"The dark slide is put into the camera through the left side, and not through the top; and the shutter is pulled out through the left side.

"The bottom of a camera may be hinged to a piece underneath, as shown in the drawing, in order that it may be easily turned round upon the tripod, and raised or lowered so as to bring a moving object into the field.

"The whole construction being now explained, the mode of using the camera is as follows:—

"First, put into its place the dark slide containing the sensitive film, and open the shutter. The reflector being down no light from the lens can fall upon the plate.

"Next open the lid which covers the ground glass, and throw over your head the black cloth which is attached to the lid, and which is large enough to fall well over your shoulders, and completely envelope the camera, all but the opening of the lens. There is nothing more miserable than a scanty black cloth.

"With the left hand you must now direct the camera towards the object, and when it is in the field upon the ground glass, focus it with the right hand upon the focussing screw.

* In the "Notes" the description is illustrated with a diagram: the points P of course refer to any part in focus on either the plate or ground glass.

"When all is ready for the exposure, take the right hand from the focussing screw and turn up the reflector with it,—or touch the instantaneous trigger which turns up the reflector.

"If the head and shoulders are well covered with the black cloth no light can get into the camera through the ground glass so as to injure the sensitive plate when the reflector is raised; but to prevent all apprehension on this score, nothing is easier than to lay a piece of orange-coloured glass upon the ground glass, which does not at all impede the focussing of the image.

"Portraits can be taken in the manner described, but there is then no necessity for the instantaneous trigger, which can be detached."

PHOTOGRAPHIC CHEMICALS:

Their Manufacture, Adulterations, and Analysis.

Sulphuric Acid—(continued).—The impurities in sulphuric acid are very numerous, and an exact acquaintance with their methods of detection is likewise of great importance. The chief are, organic matter; an excess of water (which may be regarded in the light of an impurity); hydrochloric acid, nitric oxide, nitrous and nitric acid, potassa, oxide of lead, selenium, lime, magnesia, titanium, arsenic, oxide of zinc, binoxide of tin, sesquioxide of iron, oxide of copper, and mercury; many of these bodies do not dissolve in the oil of vitriol, but merely form a sediment in it.

Organic matter is known when present by its imparting a brown colour to the oil of vitriol. It can be removed by heating the acid to the boiling point, and keeping it so till all colour has disappeared. The carbon of the organic matter will be oxidised at the expense of the acid, and will escape in the form of carbonic acid, accompanied with sulphurous acid.

Water in excess is known by its rendering the acid of less specific gravity, and also crystallizable by a moderate degree of cold. It may likewise be removed by ebullition.

Hydrochloric acid usually occurs through impurities being present in the nitre. It may be detected by treating the suspected acid with peroxide of manganese, which has previously been found to be free from this impurity. If chlorine be present in the sulphuric acid, it may be detected by the smell. Boiling the acid likewise removes this impurity; the ebullition should be continued until the distillate ceases to precipitate nitrate of silver solution. *Nitric oxide, nitrous acid*, or *nitric acid* in oil of vitriol is best detected by the addition of a solution of protosulphate of iron. The solution should be pretty strong, and should be poured on to the surface of the oil of vitriol without allowing them to mix: the solution of the protosulphate should form a layer one fourth as deep as the sulphuric acid. A red or purple colour appears at the common surface of the two liquids. Upon its disappearing after some time, agitation will restore it. Another mode of testing is to mix one part of water with 100 parts of the oil of vitriol, wait till the heat generated has disappeared, and then add the iron solution, in the proportion of one drop to five grammes of the acid. The addition must take place slowly, so that the liquid may not become heated. This reaction is so delicate, that by its means 1 part of nitric acid can be detected in 500,000 parts of oil of vitriol. The separation of these nitrogen compounds from oil of vitriol is a matter of some little difficulty. One plan is to heat the oil of vitriol with a little sugar, until the liquid, which at first turns black, begins to boil, and again becomes colourless. The presence of nitric acid in oil of vitriol may be distinguished from that of nitrous acid, and nitrous oxide, by the following characters: the addition of hydrochloric acid to the sulphuric acid will communicate to it the property of dissolving gold, if nitric acid is present, but this will remain undissolved, if only the other oxides of nitrogen are there. Nitric acid is also shown by the colour of solution of indigo being destroyed when boiled with the mixture of hydrochloric acid and suspected oil of vitriol. One of the most curious properties which a little nitric acid communicates to oil of vitriol is that of dissolving platinum at a boiling heat. This occasions serious corrosion of the platinum retorts, and consequently care should be taken to entirely remove all the nitrogen compounds before the acid is brought into contact with the platinum vessels. This is effected by adding sulphate of ammonia in small quantities to the dilute acid during its evaporation in the leaden pans. The ammonia and nitric acid, or oxide, re-act upon one another with mutual destruction, and formation of water and nitrogen gas.

Arsenic is one of the most serious impurities which can occur in oil of vitriol, and, unfortunately it is also one of the most common. It is derived from the pyrites from which the greater part of English oil of vitriol is made, and exists, for the most part, in the form of arsenious acid, although a trace of arsenic acid is likewise present. A very small quantity may be detected by diluting with twice its bulk of water, supersaturating with carbonate of potassa, separating the precipitated sulphate of potassa by filtration, and washing it with a small quantity of water. The filtrate is to be evaporated, mixed with hydrochloric acid, and thoroughly saturated with hydrosulphuric acid gas. The arsenic will be precipitated in the form of a yellow precipitate, which may have an orange tinge, if arsenic acid has been present along with the arsenious acid. Oil of vitriol is very difficult to purify entirely from arsenic. It will scarcely be within the power of an amateur to effect the purification properly. The most advisable course to pursue will be to test it for arsenic in the above manner, and if any be found to be present, to reject it at once.

Selenium is not commonly met with in English sulphuric acid, although many Continental acids contain it. Dilute the acid with twice its bulk of water, and allow it to cool, add sulphurous acid, and if there is a reddish precipitate, it is most likely to be selenium. Decant the acid from the powder and wash the latter with water. Dry it and burn on charcoal before the blowpipe. A most abominable odour of putrid horseradish will be observed if selenium be present.

Lead is frequently present. It occurs as sulphate of lead, which although insoluble in water is soluble in the strong acid. It will be precipitated as a white powder when the oil of vitriol is diluted with water containing a little alcohol. This last impurity, as well as the remaining ones, viz., *potassa, lime, magnesia, titanium, zinc, tin, iron,* and *copper,* will be left behind as solid residue when oil of vitriol is distilled. The identification of either of these impurities in the residue is a matter of no difficulty to the chemist, but to the amateur who only wishes to know if his sulphuric acid is pure it would be superfluous to descend to such minutiæ; as the presence of any residue at all, shews that the acid is impure.

Before leaving the subject of sulphuric acid a few remarks on some precautions necessary to be taken when working with it will not be out of place. It has already been mentioned that this acid is possessed of the most powerfully corrosive properties. Not only does the concentrated acid char and destroy almost all kinds of organic matter, but very dilute acid has similar properties. A drop of dilute acid allowed to fall upon a piece of linen has no immediate action upon it. The water, however, evaporates from the acid, and the latter, being non-volatile, becomes more and more concentrated until, at length, the first time the fabric is brought near a fire the last traces of water fly off, and the strong acid left at once eats the linen into holes. If any sulphuric acid should by accident fall upon the clothes, not a moment's time must be lost in copiously deluging the spot with dilute ammonia applied repeatedly until a piece of blue litmus-paper, pressed for some time against the spot gives no red tint. On no account should oil of vitriol be permitted to touch the flesh. Some persons can bear contact with this body longer than others, but in most cases severe and slowly healing wounds are the result. Plenty of cold water is the best remedy until every trace of the acid is removed. A little acetate of lead may be dissolved in the latter portions of the water which it applied, and the wound should afterwards be treated as is if it were a burn.

In distilling oil of vitriol, one or two precautions must also be taken. The boiling takes place with violent concussions and sudden bursts of vapour. To avoid the danger of fracturing the retort by these explosions it is best to apply heat only to the sides of the retort by means of a ring gas burner. The insoluble matters collect at the bottom of the retort, whilst the ebullition takes place tranquilly from the sides.

In diluting oil of vitriol with water precautions should be taken to avoid fracturing the vessel by the great heat which is evolved. The acid should be poured very gradually into the water in a thin stream with constant stirring, and the operation should be stopped now and then if the heat rises too quickly.

DEFECTS IN PAPER PRINTS AND THEIR REMEDIES

BY SAMUEL FRY.

It is rather unfortunate that photographers are apt to assume that obtaining prints from their negatives is a very simple, straightforward operation, not involving any peculiar difficulties, and which may be intrusted to comparatively unskilled hands. No error can be greater. To produce really fine paper prints requires as much chemical knowledge, as extensive experience, and as much power to grasp and overcome difficulties, as to take a good negative. We find in printing, the result of what has been justly termed the "unfortunate facilities" of photography, as in any other branch, for it is unquestionably true, that the veriest tyro by adhering strictly to the letter of any work, or instruction, he may receive on the subject, can at once produce "proofs" of some kind or other, generally sufficiently good to please his lenient friends; but if he be really discriminating, he will soon perceive that whatever may be the cause, they are not up to the standard of others.

Printing difficulties may be comprised under the heads of black spots, white spots, flatness, general poorness of tone, mealyness, and measles.

In attempting to explain the cause of these drawbacks, I conclude, as before, that the toning and fixing are made two distinct operations, that it is, I am sorry to say, but too true that many professional photographers still tone by the old hypo, but their prints may be selected amongst any number of others, from their yellow tone and general want of brilliancy, as compared with alkaline-toned prints.

Black spots are in a great measure caused by particles of metal in the paper on which the proof is taken, but another prolific source is from allowing the proofs before toning to lie exposed to air on a wooden or painted surface, as for example a drawer or cupboard; they should be invariably kept in a portfolio; these spots are also caused by keeping the sensitized paper or proofs in a tin or other metal box, instead of between the leaves of a blotting book or other convenient place of the same description. These spots are of necessity almost fatal to the value of the print affected, as it is scarcely possible to conceal or obliterate them from whatever cause they may arise.

White spots are commonly occasioned by a bubble of air being under the paper during sensitizing, but are also frequently caused by dust in the printing frame, or small pieces of paper or wood being between the negative and the sensitized surface during printing, also by dirt on the outer surface of the glass of the frame, which casts a shadow on the inner surface; these causes of necessity suggest their own remedy.

Flatness, when not caused by poverty of the negative, may arise from the silver bath being below the normal strength of 60 grains to the ounce of water, also from the print being insufficiently exposed; again, the sensitized paper may have been kept too long before use, or during printing. The inspection may have been done in daylight, instead of in the dark room, thus causing a degradation of the lights of the picture, and a general want of clearness, and that crisp, sharp decision which the print would otherwise possess. General poorness of tone, perhaps grey inclining to blue, is caused by a too prolonged immersion in the toning bath. As a rule, I find that prints assume their real colour in the subsequent bath of hypo, and will, if the paper contain a suitable proportion of salt, bear removal when a rich brown is attained, but to support this treatment effectually, they must be vigorous negatives, and well printed up.

We next come to mealyness, this greatest trouble of printers under the alkaline system, and one which will never be really removed until a new or improved surface be given to the plain paper before albumenizing, or until some substitute for albumen be obtained, giving a more homogeneous surface, and no liability to run into streaks of varying thickness.

The simplest description of mealyness is that some portions of the picture tone sooner than other parts. With the old hypo bath it was comparatively unknown, because the action was so slow that the solution thoroughly penetrated all parts of the print before toning commenced. We may, therefore, follow out the same principle by making one toning bath weaker when a sample of paper has this failing, and thus allowing, say, from a quarter of an hour to 20 minutes for the toning; also, the bath made with acetate of soda seems to give a greater immunity from mealyness than when prepared either with carbonate, or phosphate, and, therefore, the means I recommend are to use a weak bath of—

Gold	1 grain
Ac. soda	10 grains
Water	1 pint,

and allow the prints to tone slowly in this. It is, I regret to say, the case that there are many papers with which one cannot work without mealyness, but these may often be used for large prints containing much detail and variety of subject in which the inclination to unequal toning will, at all events, be much less apparent than in small stereoscopic or card portrait pictures.

Measles are generally caused from the paper having floated an insufficient time on the bath, and if the bath be also a weak one the evil is much aggravated; they are also caused by the albumenized paper being damp from keeping it in a humid atmosphere; few things are more hygroscopic than unsensitized albumenized paper; it loses its gloss, becomes limp, and the albumen is easily removed from the surface. Imperfect fixation, from the use of exhausted or weak hypo, is the most common source of measles. New hypo, not weaker than one ounce in five ounces of water, should always be used, and the prints should be well immersed and kept moving to prevent them sticking together. Allow me again to reiterate that no error can be more fatal than to conclude that printing is of secondary importance; few negatives, comparatively speaking, ever really have the best prints they are capable of giving, produced from them. If photographers took as much pains with their printing as they do to obtain negatives, a great alteration would soon be seen.

THE INTERNATIONAL EXHIBITION OF 1862:

What are the Arrangements made for representing Photography there?

BY C. JABEZ HUGHES.*

A few days since I took my walks in the neighbourhood of South Kensington, and for the first time saw the great building in the course of erection for the International Exhibition of 1862. I was surprised, astonished, and delighted. I was not prepared for the great progress made. In my mind the intended Exhibition had been a vague, indefinite, unsubstantial possibility; a thing requiring much more talk, and thought, and calculation, and noise, and bother, and puff, and advertising before it could take a material existence. Yet there the great fact stood before me, and a very great one it is. As I wandered down its great length, and gazed on the stupendous crystal towers in the course of erection, I began to realise the vastness and grandeur of the scheme. As the shell typifies the fish, as the cast indicates the model, and the house the tenant, so surely does this vast and grand building imply the magnificent collection of the world's choicest products, speedily to be there collected. With an undying remembrance of the glories of 1851, with a vivid recollection of the Exhibition of Dublin, and the Art-Treasures of Manchester; deeply impressed with what has been done on the *Champs Elysées*, and with what is perpetuated at Sydenham; with these souvenirs fresh in my mind, I look to the new exhibition to eclipse them all.

* Read at the meeting of the South London Photographic Society, Oct. 10.

It cannot have the startling prestige of 1851; nor, falling on less pacific times, will it pretend to herald in a delusive peaceful millenium, but it comes at a more stirring and energetic period, and will bear many of the fruits of which the former great Exhibition only laid the seeds.

Vast and varied however as this mighty collection will be, its distinguishing characteristic will consist in the grand display of Modern Fine Art. All nations will contribute examples of their greatest living and recently deceased artists. La Belle France, young Italy, esthetic Germany, clever Belgium, realistic Holland, even distant Russia, will send their trophies of science, and art, and industry, to compare with the treasures of Old England.

And when this grand collection is brought together; when this galaxy of talent is convened; amidst this very constellation of Genius, we, as photographers, naturally ask, how will our favourite pursuit be represented?

When all the sister Arts are assembled in their choicest and most brilliant attire; Painting glowing with all the charms of colour, and Sculpture in her purest forms: the Industrial Arts, each in its most attractive guise; Music with enchanting strains, and Poetry beautifying and idealising all—in this gay assemblage, and in the presence of Wisdom, and Rank, and Wealth, and Youth, and Beauty, where shall we look for our idol Art?

Will it occupy the distinguished position to which it aspires? Shall we see it appear with its credentials in its hand, and claim a place among the highest Arts, and will its claims be acknowledged and itself welcomed into the inner and charmed circle as the most youthful of the Arts? Will the protecting geniuses Wisdom and Beauty, recognize this young offspring of Science and Art, and placing it on its pedestal call upon all to pay it homage? And, clothed in the robes of beauty, with the effulgent star of Truth on its brow, shall we witness its apotheosis?

Or, to employ humbler imagery, shall we find Photography at the New Exhibition like the celebrated five wise virgins? Will its lamps be trimmed, and will it be ready and equal for the occasion? Or, will it be found without preparation, with no oil in its lamps, so that, like the five foolish ones, when the cry comes it will not be prepared to go in, and then the door will be shut. Should great exertion be afterwards made, large lamps with abundance of good oil provided, and much knocking at the door be made, it will be very mortifying to be told by the Commissioners, We know you not; you complied not with our regulations; you have been more foolish than the foolish virgins, you knew both the day and the hour, and availed not yourselves of the knowledge, and you must submit to the consequences.

It is to be hoped that little of this mortification will be felt, and that photographers, like wise virgins, have availed themselves in time and duly applied for space, and that they have determined to send the best things they can produce. But whatever photographers, individually, have done, in their collective capacity nothing, or worse than nothing, has taken place to represent photography in such a manner as to be creditable to the art or honourable to the nation.

For foreign photography I have not much fear. I have every reason to believe it will be numerously and worthily represented. The same causes have not been at work with them to damp their ardour and check their enthusiasm,

It is for the English portion that I entertain fears. At least ten years will elapse before a similar occasion will occur of displaying the immense improvement in our art, and its endless applications. It was a great misfortune that the Commissioners should have adopted so unfortunate a classification, so far as photography was concerned; but it was a still greater misfortune that the Council of the photography could see no other way out of their position than to abandon the project of a Committee of photographic gentlemen, to manage the photographic section, because the Commissioners would not cede the point in dispute. It is to be lamented that the Council, after having so argumentatively established their case, could not accept the proposal of a separate department for photography. Although photographers are well convinced that this art is entitled to rank among the Fine Arts, yet when the position is controverted they could hardly be expected to be allowed to be judges in their own favour. The Commissioners are not the sole persons who deny it the right. The great body of artists, and they are popularly supposed to be the best judges, say that our art has no place among the Fine Arts When, therefore, the Commissioners offered a separate department they practically said, "We will not debate the question with you, but we will supply you with the means whereby you can substantiate your position; and if it prove that we have done you an injustice, the more credit will be due to you by proving that we, in common with many more, have not sufficiently appreciated this new and rapidly improving art. The verdict being given by competent parties in your favour, we will acknowledge that you have fairly won your spurs, and in future we shall freely accord that place to photography which it has shown itself worthy to hold." The Council, however, saw fit to stand on their dignity, the Commissioners felt they could yield no more; and between these two stools photography has fallen to the ground. The opportunity that was afforded of enlisting the sympathies of all British photographers to exhibit the usefulness and beauties of their art to its fullest extent, is past.

How much more effective the Exhibition would have been if a central committee had been established with a comprehensive plan, and supported by the cordial co-operation of local committees, carrying out the details, as compared with individual efforts working without purpose or arrangement, no one can tell; but the results would certainly be very different.

There can be no doubt a great opportunity is lost, and however photography may gain, nothing like the benefit will arise that might have occurred had full advantage been taken of this rare occasion. In the 1851 Exhibition, photography was a crude, undigested mass. Portions were to be found here, there, and everywhere. Shimmering and glittering on silver, hard and wiry on albumen, woolly and foxy on paper. Without natural guardians, it wandered about the great building, having a home nowhere. It made a small lodgment among the ivory miniatures, was principally to be seen amongst the stationery, was frequently cropping out of the foreign departments, and formed the only brilliant display in the deserted settlements and backwoods of the American department. In 1861 it has its natural protectors; they, however, are not adroit enough to keep it in their own hands, and cruelly allow it to sink or swim, rather than yield a little of their own opinion. When we last assembled here the question was, should a committee be appointed to arrange the proper display of photography, seeing that the latter was placed in a mechanical department; against this we all remonstrated. As I have already said, another offer was next made, that as photography was *sui generis*, to provide a separate place for it, an offer which, under protest especially, might, in my humble opinion, without any loss of dignity, have been accepted, but this also was rejected; and matters are worse than at first, viz., our pictures are still left in their original mechanical location, without even the committee of photographers to overlook, arrange, and advise.

Thus the matter stands; while all other portions have gentlemen to superintend them who are learned and interested in the various details, poor photography stands alone. Who is to take charge of it, or whether anyone is to take charge of it, we do not know. Whether it is to be placed under the tender mercies of the gentlemen who arrange the agricultural instruments or the ship's tackle, we are in doubt; but as the pictures can neither arrange nor hang themselves, it is but natural that we should desire to know to whom they are to be entrusted. It is also of the highest importance that we should know whether any plan or method is to be devised or recommended for intending exhibitors to conform to, so that the few fine days that may occur before the period for sending in pictures may fully be taken advantage of. Will there be any endeavour to form an *historical* collection? Is it desirable to forward the *curiosities* of the art? Ought *processes*, as such, to be specially illustrated? Will morbid photography be admissible, that is, *failures* to which reliable causes may be assigned? Will limitations be assigned as to size, quantity or number of pictures? Are *negatives* to be sent as well as positives? Will any means be taken so that an instructive collection of the various dry processess will be seen? Is there any principle of classification or arrangement to be adopted? Are pictures to be grouped according to size, or subject, or exhibitor? In fact, questions crowd on my mind arising from a natural anxiety that justice should be done to photography, and from a fear that its arrangement may be entrusted to hands that even with the best intentions, may not be able to grasp the character of the subject. Had a committee of gentlemen of well-known ability been appointed, these doubts and fears would not have arisen, for the characters of the committee would have been a guarantee. As matters stand, it is extremely desirable that photographers should be furnished with this information.

It must be borne in mind, that this coming Exhibition is no common one, and that many variations may be required from the usual photographic displays. Our usual Exhibitions are visited chiefly by amateur and professional photographers, their friends and acquaintances, and a small quantity of dilletante persons; the generality of folks never see, and seldom hear of them. But in the forthcoming great show, the great stream of the people will flow past, and tens of thousands will see them who never saw a collection of photographs before, and never will again. For this reason it is I regret that the occasion will not be improved to the fullest extent.

But though it is no use making useless regrets, it is of the utmost consequence that the Commissioners should quickly appoint some gentlemen of sufficient knowledge and technical experience, and, if possible, whose names are well known to photographers, to take charge of, and arrange the whole. It should be their duty to form a comprehensive plan, sufficient to embrace foreign as well as home photography, and to carefully follow that out. Whatever directions are intended to be published for the guidance of exhibitors should be issued as soon as possible, so that all reasonable aid may be afforded them. It is to be hoped that, undeterred by the adverse influences that have been in operation, our best men have been alive to their interests, and have secured adequate space, so that they may honourably shine by the side of their foreign brethren. Lamentable, indeed, will it be, if in our own Exhibition we alone are found wanting. What shall we say for ourselves, when all other artists are striving their utmost to sustain the national honour, that photographers alone make a mean display; and little short of national disgrace will it be, if in the land of Herschel, and Brewster, and Wheatstone, and Hardwich, if the works of her Bedfords, and Williams, and Mudds, and Mayalls, and Heaths, and Claudets, and Lacys, and kindred artists, are not present in sufficient abundance to do honour to the great names of Talbot and Archer.

MATHEMATICAL PHOTOGRAPHIC INSTANTANEITY.

As a point is to magnitude in geometry, so is instantaneity to time in photography. Time is duration with beginning and end, but instantaneity is beginning and end without duration.

All operations in chemistry, optics, and mechanics, requiring time for their operation, strictly speaking there can be no such thing as an instantaneous photograph executed by man or physical means, until light, enfranchised from that which restricts its velocity to 98,000 miles in a second, becomes as free as thought to visit the most distant object as quickly as the nearest.

Popular Photographic Instantaneity is as latitudinarian as the terms long and short, some holding that an instantaneous photograph is one taken in a second; others, as quickly as the dark slide can be lifted up and down, or the cap of the lens taken off and on, or "as quick as possible."

The writer, in his search after the "instantaneous," recollects being enticed into a photographic studio in Regent Street, by "*Instantaneous portraits taken here*," but upon trial the "*instantaneous*" turned out to be a thirty seconds' affair.

The best, oldest, and most reliable test of instantaneity, in a popular sense, is undoubtedly "the twinkling of an eye," the quickest as well as most uniform voluntary movement common to man and beast. It has been stated by scientific Opticians that the image of an object once falling on the eye's retina, cannot be removed therefrom in less than one-tenth of a second. The twinkling of an eye comprises a closing and opening movement during which the eye is darkened for the space of one-tenth of a second, The very trifling obscurity of vision which takes place during this natural twinkling of the eye with most persons when reading, countenances the hypothesis that this movement was adjusted with a regard to the time which light rests on the retina. Taking these two remarkable coinciding phenomena as data whereby to distinguish practically the instantaneous from other movements, we shall find that as a flash of lightning passes unperceived by eyes happening to be in the act of twinkling at the time, therefore lightning may be regarded as instantaneous, as whether it passes in the tenth of a second, or less than the ten-millionth part of a second, the unassisted eye has no means of ascertaining. On the other hand, a movement which is begun and not ended during the twinkling of an eye (that is in the one-tenth of a second), as it cannot escape the observation of a looker-on, therefore such a movement in a popular sense is not instantaneous, seeing the unassisted eye can take the measure of its duration.—*Skaife's Guide to the Pistolgraph.*

CARTES DE VISITE.

(*Condensed from the Art-Journal.*)

Never was a nomenclature based upon the principle of *lucus a non lucendo* exemplified in a more characteristic manner, than in the instance of the delightful photographic miniatures that now are universally popular under the title of *Cartes de Visite.* They are neither regarded nor used as visiting cards, nor does anyone think of applying to them a plain English designation to that effect: and yet everybody understands a *Carte de Visite* to be a small photographic portrait, generally a full length, mounted on a card; and everybody is also equally anxious both to obtain his or her own miniature, executed in this style, and to form a collection of these *Cartes de Visite*—the portraits of everybody else. For the present, apparently, the most popular, the most deservedly popular also, and by far the most numerous class of English portraits must be content to be known by an inapplicable, and indeed an unmeaning French name: perhaps, in due time, the *carte de visite* fashion of to-day may subside into what we certainly hope will prove to be an enduring admiration for sun-miniatures—portraits, that is, of precisely the same order, but bearing a simple and becoming English title.

Meanwhile, however strange the misapplication of the term *carte de visite* may have become in its prevailing use, the photographic miniatures themselves, certainly, are most felicitous expressions of the photographer's wonderful art. They are such true portraits, and they are so readily obtainable, and so easily re-produced, that they may well aspire to become absolutely universal. Few, indeed, are the individuals whose personal lineaments are not regarded with especial sympathy by at least a small group of loving friends; and, on the other hand, no less limited is the number of those persons who do not cherish the associations that are best conveyed by means of the portraits of the loved, and esteemed, and honoured. And then we all have a peculiar liking for our own portraits, and we always like them to be liked. So sun-miniatures are certain to prevail. Already they have attained to a position in the front rank of the Art-productions of the day, and, from their present eminent condition of popular approval, they are constantly making still further advances; and they will, in all probability, continue to increase in public esteem so long as they are executed with skill and feeling, and they remain true to the simple fidelity of genuine portraiture.

It seems but the other day that photography itself first appeared amongst us, sent as on a fresh sunbeam, and took its place with the most recent of the Arts; and now we see several distinct classes of photographs, to each of which may be properly assigned the rank of an independent branch of photography. These *cartes de visite* in themselves constitute what we may even entitle an Art. They multiply national portrait galleries *ad infinitum.* They produce the family portraits of the entire community. They form portrait collections, on a miniature scale, but with an unlimited range and in every possible variety—family collections, collections of the portraits of friends, and of celebrities of every rank and order, both foreign and of our own country. Nobody now needs to inquire what such-or-such a person may be like, or to be left to such surmises as written descriptions may convey of features and figures that cannot be actually seen. An ubiquitous *carte de visite* can always find its way with certainty and speed, and it is the best of all possible introductions, as it is the most agreeable of reminiscences. When our friends leave us, they leave with us these precious images which we can always and everywhere carry about with us, to feast our bodily eyes with their graphic representations, as memory is able to treasure up and to pass in mental review incidents that the past has taken with it, and words whose echoes have long ago died away. And when fresh connections are formed, or when new links are added to old chains, the ever-available *carte de visite* is ready to make known to us here at home, in *propriâ personâ,* a far-away new daughter-in-law, or the number one (or the number whatever you please) of another generation. We now look with commingled surprise and scorn at the painful efforts at family portraiture that preceded the photographic era, and which resulted in either pallid libels, brush-produced upon ivory, or black paper reductions of shadows in profile, cut out with scissors, and closely allied to architectural sections. These black paper enormities admonish us that but a single step intervened between that first tracing of a much-loved shadow on the wall at Corinth, and the almost breathing and sentient portrait of the *carte de visite.* And, let us be duly grateful to him; the same sun that inspired the Greeks with the happy thought of fixing a shadow, now gives us our perfect portraits—portraits that would have turned the very brain of Apelles himself, and which in common justice we ought to have called, not photo, but helio-graphs. And not only in the case of black profiles and feeble miniature "likenesses" does the *carte de visite* at once effect the most marvellous of revolutions in collections of family portraits, but also in comparison with the highest orders of miniature-pictures the little sun-portraits are well able to maintain their reputation. Thorburn gave up his miniatures just at the right time, as if influenced by a prescient impulse that an artist more potent even than himself would soon be at work, executing first-class miniatures for the million, and reproducing them with a corresponding ease and rapidity, Elaborately painted miniatures now are artistic curiosities, few in their numbers, and rather calculated to associate the present with the past, than to convey ideas in conformity with the spirit of an age that looks forward with so ardent a gaze. Very beautiful little objects are those miniature paintings, when they are really the work of true artists, and they always will be regarded with a loving admiration; but, reversing the process that acclimatises plants, they have grown into exotics, while the *carte de visite* are favourites that find a congenial soil in every spot, and flourish in every region, multiplying their numbers daily by tens of thousands.

In addition to what they accomplish in providing for us all such delightful miniatures of our families and friends, and of our own selves also, *cartes de visite* confer positive blessings in supplying us with faithful and thoroughly artistic portraits of individuals for whom, without including them in the ranks of our personal friends, we entertain a profound respect and perhaps a warm regard. And the same feeling which invests with their own peculiar charm the portraits of those whose lot in life is cast in close connection with our own, expresses itself with a suitably modified earnestness in reference to the portraits of the honoured, the respected, and the admired. Second only in our esteem to our private portrait collection, is what we distinguish as our collection of portraits of public personages. Here *cartes de visite* expatiate in a field that positively knows no limits; and here also they exhibit in the most striking aspect their peculiar faculty of uniformly excellent reproduction.

Whatever our special taste in Art, or literature, or science, we can select *cartes de visite* which will form for us our own collection of the portraits of the artists, the authors, or the philosophers whose names to us are as "household words." It is the same in politics—a *carte de visite* is equally really for us, whether we prefer Derby or Palmerston, Lyndhurst or Brougham, and in either case the portrait sets before us the very man. We might multiply examples in every possible department of public life; we might single out our most eminent officers and our ablest civilians—we might select the individuals who signally adorn the professions, whether the church, the bar, or of medicine, and we might pass on to public favourites of every varied calling; but, without attempting any such detailed illustrations of the versatile capacities of *carte de visite* miniatures, we are content to refer to the personal introductions which these wonderful portraits have effected for us to two individuals only—two men, not Englishmen, but men whom Englishmen delight to honour, the one still living in the fulness of his fame, and the other lamented as well as honoured—Garibaldi and Cavour.

The extraordinary popularity of the photographic miniatures we are considering, naturally has produced a very numerous array of professing artists, ready to execute whatever *carte de visite* may be required. In London alone many hundreds of establishments of this class exist, and the greater number of them flourish; and, in like manner, scarcely a town can be found which does not possess its own resident photographer. It must not be supposed that all these artists by any means approximate to a common standard of excellence in their several works. We are not able to express any opinion relative to very many provincial photographers; but we certainly have seen many *cartes de visite* from the provinces, that are highly creditable to the artists by whom they have been executed. In London there are many photographers of the highest eminence, all of whom produce in vast numbers these ever-attractive miniatures; and the able artists are well diffused over the metropolis, so that there exists no difficulty in finding out an establishment at which even a stranger to London may have his miniature well taken in photography. Even more numerous than the establishments for producing them are those at which *cartes de visite* are offered to the public for sale. They enjoy, too, a peculiar reputation, as it would seem, which leads them into a strange association with other objects, with which they would apparently have no kind or degree of sympathy. These photographic miniatures are exhibited and sold by persons whose establishments have no other connection with works of Art. They are in universal request, however, and so everybody thinks that he may quite consistently take a part in providing the requisite supply; and, if these portraits thus often find themselves in unexpected association with objects between which and themselves there can exist no possible sympathy, still more singular is that association which is apparent in the portraits displayed by *cartes de visite*, where they stand at the windows in long rows, tier above tier. The windows of he Photographic Institution, adjoining Bow Church, in the City, for example, afford abundant materials for reflection upon the contingencies of unexpected aggroupment. There, and in many other places also, the most curious contrasts may be drawn, and the most startling combinations effected. Of course all these combinations are purely casual; but it is their casual origin that constitutes their singularity; and, after all, when even the most hurried of passing glances reveals to us fac-simile images of Lord Shaftesbury and Cardinal Wiseman, and of the French Emperor and Sims Reeves side by side, with those of Florence Nightingale and Blondin and Professor Owen forming a trio, we are reminded in a manner the most impressive that *carte de visite* miniatures are creations of the present day, portraits of our own actual contemporaries. These photographs are essentially novelties—they belong to the present; with the past, except with so much of it as has been very recently the present, they have no connection whatever; as we have said, they are contemporary portraits—portraits of the men, and women, and children of the living generation. And the strange composition of many groups of these *carte de visite* portraits may not inaptly suggest to the originals that they, like their portraits, might take no harm from associations which now they probably would regard with sentiments of aversion and even of horror: indeed, much of mutual benefit might be derived from very many persons coming into contact one with another, who now stand sternly apart; and certainly, very many persons might confer most important benefits, even though they received nothing more than a fresh lesson in experience, through occasional association with both classes and individuals that now are absolutely unknown by them.

We cannot take leave, for a time, of these most interesting photographs, without adverting to the skilful manner in which albums and other receptacles for the portraits have been produced. The novelty of the arrangements for introducing the cards, and the felicitous manner in which the portraits are at once displayed and preserved, merit the strongest commendation. These books and cases abound, in every variety of form and size, and style of embellishment. Like the stereoscope, at least one of them must find its way into every family circle; and, without doubt, both the stereoscope and the *carte de visite* album will never cease to enjoy the hearty and cordial sympathy of every intelligent individual.

Proceedings of Societies.

THE MEMORIAL OF THE SOUTH LONDON PHOTOGRAPHIC SOCIETY TO HER MAJESTY'S COMMISSIONERS FOR THE INTERNATIONAL EXHIBITION OF 1862.

The South London Photographic Society having noticed with concern that notwithstanding the season for successful photographic operations is drawing to a close, and the period of the International Exhibition is rapidly approaching, no regulations or instructions for the guidance of photographers have yet been published, nor has any committee or list of gentlemen to whom the arrangements for controling this department have been entrusted, been announced. The South London Photographic Society had hoped at their last meeting that the negotiations then pending between Her Majesty's Commissioners and the London Photographic Society would have terminated in the appointment of a committee, but such negotiations having unhappily failed in producing this result, the South London Photographic Society take the opportunity at this their first meeting after the summer recess, of expressing their approval of the decision of Her Majesty's Commissioners as regards the separate department promised to photography, and of respectfully representing the importance of the following considerations:

That a committee of gentlemen familiar with and interested in photography, and of well-known attainments in connection with the Art, should be appointed and announced to photographers, as having the direction and control of the Photographic Department.

Photography comprehending, as it does, various and distinct departments, such as illustrate its scientific progress and its various artistic and economic applications in portraiture, landscape, architecture, astronomy, magnetism, meteorology, physiology, psychology and many other departments, and a proper arrangement of all these departments depending on technical familiarity with the Art generally, renders the appointment of such committee of vital importance.

That to secure a successful representation of the Art, a comprehensive plan of arrangements should be devised and published, in order that photographers may, in their preparations for contributing, conform thereto, and so co-operate in the production of a successful result honourable to this country.

That whilst many other important considerations, in connection with this subject crowd on the mind of the memorialists, they do not deem it prudent here to trouble Her Majesty's Commissioners with questions of detail. But beg once more to press upon their attention that the successful issue of this department of the Exhibition depends almost entirely upon the decisions which shall be now made and published regarding it.

The South London Society, in conclusion, beg to tender such service as they may be able to contribute to aid Her Majesty's Commissioners in carrying out any decisions at which they may arrive in relation to this important subject.

NEWCASTLE-UPON-TYNE PHOTOGRAPHIC SOCIETY.

THE first monthly meeting, after the recess, of the Newcastle-upon-Tyne and North of England Photographic Society was held in the Tower, New Bridge Street, on the 4th inst., Mr. P. M. LAWS in the chair.

A letter was read from Mr. Thomas Sutton, of Jersey, the late lecturer on photography, in King's College, London, in which he kindly promised to send a paper to be read at the November meeting.

The secretary called the attention of the meeting to a new camera, by Mr. Sutton, for taking instantaneous pictures. He spoke highly of the improvement as one very valuable, and well worthy the attention of photographers generally. Mr. Birnie described the part of the camera in which the novelty consists, as given by Mr. Sutton in the "Notes."

After some further conversation on the subject the proceedings terminated.

Correspondence.

TAXES FOR PHOTOGRAPHY.

SIR,—As a travelling photographer, I fancy that the vigorous crusade which is going on against us poor sinners, is not altogether guided by charitable motives. I think that it must be admitted that there are as many fixed resident "bunglers" who are, and ever will continue to be, a disgrace to the profession, as there are "travelling bunglers," and therefore beg to submit that taxing one and not the other, would be very unjust, and would fail to cure the evil so much complained of. Far from escaping expenses as W. B. N. would have it, I contend that travelling photographers are at more expense than fixed residents. My own for the past year are for moving twice, cost of repairs, &c. and interest ($7\frac{1}{2}$ per cent.) upon money laid out upon the building the two vans, £61 7s. 6d. Very few residents in provincial towns pay more than this sum, for *rent* and *rates*. I have nothing new to propose, although I must beg to disagree with W. B. N. I see no plan like that suggested by yourself, *i.e.*, examinations, &c., to protect the dignity of photography. Trusting you will pardon me for thus intruding upon your space, I am, very respectfully, J. M. P.

Oct. 8th, 1861.

Hints to Operators.

ECONOMY IN GLASS PLATES.—The use of patent plate glass for large sizes, especially where the number of negatives accumulated is great, soon becomes both to amateur and professional a very serious item of expense. The great objection to the use of flatted crown is, not the quality of the surface, which is often as good as that of plate, but the chance of breakages in the pressure frame. By means of a very little extra trouble, this risk may be avoided, and the expense of patent plate escaped. The real proportion of breakage in flatted crown is comparatively small, the difficulty consisting in the fact that such breakage may occur in a valuable negative. This then may be avoided by taking each plate of flatted crown and trying it in the pressure frame before using it. Those that will not stand the pressure will break and the fragments may be used for other purposes. Those which bear the test once may be expected to do it again, and negatives may, without much risk, be produced on them. White glass should be avoided for negatives, as it is apt to sweat and cause the film to crack.

LIGHTING AND POSING.—Always avoid a window in front of the sitter. Too much front light is fatal to the perfect modelling, and has a tendency to give a flat, broad effect to the features, and make the eyes light, fishy, and expressionless. A direct vertical light, on the contrary, makes the eyes heavy and dark, and casts shadows under every projection, brows, eyes, nose, and chin. Where a profile is chosen, and it might more often be used with good in photography than it is, the face should be turned somewhat from the light, in order to get fine modelling. Howard, in his *Imitative Art*, says, "A profile will be made most intelligible by introducing the light rather behind the head, so as to throw the receding boundaries of the front of the forehead, eye, cheek, nose, and chin, into a half tint. The principal lights will be on the upper part of the temples, the cheek-bone, and the ear; and the principal shadows under the hair, upon the cheek and temples, and under the eye-brow close to the nose. The whole of the front of the iris of the eye will be light, except close under the eyelashes. The pupil of the eye will be scarcely visible, but the eyeball will appear darkest where the pupil is known to be.

ALCOHOL IN THE DEVELOPER.—It is very common for the various formulæ given for developing solutions to contain a specific quantity of alcohol, as though it were a necessary part of the developing power. Its real use is simply to cause the developer to mingle freely with the nitrate of silver solution on the plate, and thus to flow without greasy-looking lines, which would cause stains of unequal development. When the nitrate bath is new, the developing solution should contain no alcohol, as its presence in the developer would cause the very defect it is usually intended to prevent. It is only when the bath has acquired a little ether and alcohol from the continued immersion plates, that alcohol should be added to the developer, and then of only just in the proportions necessary to suit the condition of the bath. For this purpose methylated spirit will answer just as well as pure spirits of wine or alcohol.

Miscellaneous.

PHOTOGRAPHING FROM BALLOONS.—At a recent meeting of the American Photographical Society, the President read a copy of a letter which he had addressed to the Secretary of War, stating the opinion of the society that photographs might be taken from balloons which would be of great value in military reconnoissances, and offering the services of the society in aiding the Government to employ this valuable power. The President remarked that though the letter was sent more than a month ago, he had received no answer to it. This neglect he attributed to the overwhelming mass of business which the Secretary of War has on his hands. Mr. Seely remarked that probably the secretary was not aware of the practical value of the aid tendered. A photograph from a balloon would be a perfect and minute record of the country observed, which might be examined under the microscope, and details brought out which would be invisible from the balloon. Mr. Tillman regretted the inattention to their offer, but could see nothing further for the society to do in the premises.

NEW PASTE FROM WOOD.—A new paste, designed to take the place of glue and starch for many purposes, has been lately manufactured. It is made as follows: The wood is first reduced to fine shavings, then these are boiled in a strong lye of caustic soda or potash until all the fibres are separated. The best woods used for making the paste are poplar, pine, beech, spruce pine, and most woods termed "soft." When boiled, a sufficient length of time for the softening of the fibres of the shavings, the fibrous matter is withdrawn into open vats, and exposed to the air for several days, when it ferments, and the whole mass becomes soft and glutinous. It is now cut up in machines like those employed in paper mills for cutting and grinding rags to make paper stock, when it becomes fit to be boiled in water, and is converted into a vegetable cement.

DECOMPOSITION OF GUN-COTTON.—At the last meeting of the Academy of Sciences, M. Bonnet communicated certain remarks on the spontaneous decomposition of gun-cotton under the influence of diffused light. The gun-cotton on which he observed this action of light had been prepared in 1856—that is, four years before its decomposition. That which became first decomposed had been prepared with a mixture of nitrate of potash and sulphuric acid, while another sample, which was decomposed later, had been prepared with a mixture of nitric and sulphuric acid. In both cases the decomposition was preceded by the appearance of red vapours; but in the first case the action was much stronger, since the stopper of the phial was forced out, and the neck was cracked. In the same case the residue of the decomposition had the appearance of a substance which had once been liquid, being full of solid bubbles; in the other case, on the contrary, it was compact and strongly agglomerated; in both cases the sides of the phial were covered with small crystals of oxalic acid. The atmosphere of the second phial was acid and attracted water; the acids it contained were carbonic and formic acid.—*Mechanic's Magazine.*

Talk in the Studio.

Stereographs of Cornwall.—Mr. Wilson has, we understand, taken some instantaneous negatives of the Land's End, Logan Rocks, &c., but although he waited three days, could not, on account of the fog, get a picture of St. Michael's Mount. He intends, we are informed, to visit Cornwall at some future time to complete his views of the Cornish western scenery. These pictures should be in every collection.

A Hint to Photographers.—In a recent article in the *Cornhill Magazine* on "Physiognomy," attention is called to the important contributions photography can make towards establishing a systematic physiognomical science. The following paragraph from the article will interest our readers :—"It is necessary to point out that the physiognomist has never yet had adequate materials wherewith to build up a science. The diversities of physiognomy are infinite. In the whole visible world there is no class of appearances so varied, and in their significance so subtle as those of the human form. Fuseli wrote on one occasion :—'Let the twelfth part of an inch be added to or taken from, the space between the nose and the upper lip of the Apollo, and the god is lost.' That is too strong a way of putting it. The god remains in the Greek marbles even when his nose is broken off. It is not in any one feature that he resides, but in all. Let the statement pass, however, as indicating in a rough way what a clever painter and man of genius thought as to the astounding differences of character expressed in evanescent differences of external form. Now, in order to be able to generalize with anything like success all these subtle shades and variations of contour, we require an immense number of accurate observations, and to have them side by side before us, so as to be able to form a comparison. This we have never yet had. Lavater gives a great number of portraits, and he had many more in his collection, but he was always complaining that they were unreliable. In this one the nostril was out of drawing; in that the chin was a falsehood; here the eye was uncertain; there the hand was nothing at all. Especially in the hand have the portrait painters failed, and there is nothing that the physiognomist is so much in want of as a good collection of hands. It is to be hoped that the discovery of the photograph will prove to be the dawn of a new day for him. As the science of chemistry was nothing until a perfect balance was invented, and as the science of physiology was really unknown until the microscope was improved, so it may be that the faithful register of the camera, supplying us with countless numbers of accurate observations, will now render that an actual science which has hitherto been only a possible one. We shall get a great variety of heads, and be able to classify them according to each separate feature, and according to each leading trait of character. Above all, when once the attention of the photographers is called to the want, we shall begin to get hands—hands by themselves, and hands in connection with faces. These are facts which we have only now for the first time the means of getting in sufficient number. The portraits we have had have, for accuracy, not less than for number, been very insufficient. It is not so much portraits that we have had, as engravings of portraits, and engravings after engravings, the representation being thus at third and fourth hand."

To Correspondents.

H. Newman.—See recent articles on printing and toning in our pages by Mr. Leake and by Mr. Fry. There are various modes of transferring the film from glass to leather, &c. The following is a good method :—Take the picture with a strong-bodied, tough collodion, and after completing, let it dry. Then take alcohol to which nitric acid has been added in the proportion of about 10 drops to one ounce, and pour on and off the film a few times, and treat the leather the same way. Now place the film in contact with the leather, taking care to avoid air-bubbles; and place them in a pressure-frame for about half an hour. On removing the leather the film will leave the glass and remain attached to the leather.

X. Y. Z.—The best method of dealing with a scratched negative is to touch out the defects with a suitable water-colour. Cadmium yellow is very good for the purpose. The spots in the print are then white, and are easily touched out so as not to show. 2. In mounting stereographs it is easy to put each half in the proper place without testing. See that you have always about 2¾ inches from centre to centre; and if there be a little more of one side of the subject in one print than the other, see that the excess on the right picture be on the right side of that picture, and *vice versâ*. You will find this answer as a general rule.

W. Bircham, jun.—The recent postal arrangements with France extend the facilities of the book-post to that country. We have not yet seen the rate of charges. Your stereographs will be noticed shortly.

Nib Stanni.—We are pleased with your letter. It is conceived in the right spirit. Thank you for the paragraph.

G. E. W.—We can only counsel persistent application to the Postmaster-general.

E. Hanaway.—Consult our advertising columns, and procure the catalogues of various houses. We cannot here supply lists of prices.

F. Y. B.—The best means of enlarging on to paper from a small negative, is by the solar camera. Failing that, and following the plan you have been trying, you require all the light you can possibly get. If you could contrive to point the camera containing the negative to the zenith, it would be best. Next to that, a clear north sky. The tracing paper will shut out a good deal of light. If you are circumscribed by the position of your room, remove the tracing paper from the hole in your shutter, and, unless it command an uninterrupted expanse of sky, place outside, a mirror of an angle of 45°, after the fashion of the "daylight reflectors." The negative should be placed in the aperture of the shutter. With bromo-iodized paper and a strong silver bath, half-an-hour's exposure in a good light ought to give sufficient image for development. The paper is more sensitive exposed wet. But the solar camera gives by far the finest results.

C. F. Riversdale.—There was a transposition of the sentence, see *erratum* below. The iodine formula in our year-book was that originally suggested by Barreswil and Davanne; that we have recently given is weaker, in order that it may be more easily managed by inexperienced hands. The proportion of acid in a developing solution must vary with circumstances. The best proportion of citric acid is one part to two of pyrogallic; but in hot weather they may be used in equal parts. In using acetate of iron, use free acetic acid, not citric acid; the proportion according to temperature and condition of other chemicals; always use the least acid that will prevent fogging and staining. The front lens of your portrait combination, reversed, will answer for views, if it be mounted in such a mode as permits its use in that manner. Beaufoy's acetic acid is manufactured of various strengths; when no strength is named you may regard it as one-third of the strength of glacial acetic acid. The articles on iron negatives will be resumed shortly.

W. May.—Received.

N.—We are obliged by the charming vignettes; they are of Blackwater if we mistake not. The negative appears to be as good as the subject is lovely. The prints leave little to be desired, and are certainly from some cause superior to the usual results from weak baths. You favoured us before with two or three copies from the same negative, which, with these, are all distributed amongst appreciating admirers of good photography. In regard to the mode of estimating the strength of solutions, a measured fluid ounce of distilled water at 60° should contain 480 grains by weight, or one ounce avoirdupois. All chemicals, in preparing formulæ, should be weighed by the same standard, so that 1,800 grains of silver dissolved in 20 ounces or one imperial pint of water, will give you correctly a 90-grain solution. That is the usual mode of estimating the formulæ.

A. Melhuish.—Received.

Old Cove.—The same bath may be used for both positives and negatives; but not with the best results for both. To produce good positives it is desirable that the bath should contain considerably more acid than for negatives. Where only a few positives are required, and first class tones are unimportant, they may be produced in the negative bath. 2. Ironing prints will improve them; but it is not nearly so efficient as rolling. 3. The best colour for a background will vary with circumstances, but a somewhat dark grey is the most useful for general purposes.

J. P. E. desires to thank E. E. L. for his suggestions a few weeks ago regarding some defects in albumenized paper. 2. The only effectual mode of getting rid of the vapours of ether in the dark room is by ventilation. Whenever it is possible, have a draught through the dark room; good ventilation is often an aid to good pictures as well as good health. We shall be glad to receive the description of your developing stand.

Spoon Plate-holder.—A correspondent writes to inform us that having, according to the suggestion in a letter in our pages some weeks ago, sent a shilling's worth of stamps some weeks ago to Mr. Rendle of Ilfracombe, for a spoon plate-holder, he has been unable to obtain either the article or any kind of acknowledgment.

S. S.—Some new rules of the Stereo Exchange Club, will probably be established shortly, and will then be published. A portrait lens may be used in a magic lantern, if you have a room long enough. Several articles on this subject have appeared in the present and former volumes of the Photographic News.

An Aspirant.—The Dallmeyer stereo lens might be used for card portraits with sitting figures, but it is scarcely well suited to the purpose. Card portraits are frequently required in a standing position, and a space of three inches on a perfectly flat field can not be equally defined all over with a lens of 4½ inches focus. Card portraits should be taken either with a lens of long focus, or with one made expressly for the purpose.

J. Linden.—We fear that there is no lens to be obtained with which you can secure a perfectly defined standing figure on a quarter plate at a distance of eight feet from the object. Twelve feet will be required at least; a greater distance and longer focus would be still better. 2. The use of ammonia before toning will make that operation slower. We do not use it ourselves. 3. The addition, of too much nitric acid to a printing bath will make the paper less sensitive and require more time in printing. You can, if necessary, neutralize with oxide of silver. 4. The print forwarded is under-exposed, and the lens is not equal to the work.

Erratum.—In our answer to A. B. C. last week there is a transposition which reverses the meaning of the sentence. For "prints should always be fixed before toning," read, "prints should always be toned before fixing."

Maxwell Lyte, Lux, S., J., L., J. Walter, and several other correspondents in our next.

*** Our Correspondents will aid us in our endeavours to solve their difficulties if they will in all cases state details of their operations when failures occur; and when referring to former articles in the News giving the exact reference. Letters intended for the Editor should be addressed expressly to him.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 163.—*October* 18, 1861.

THE PHOTOGRAPHIC EXCHANGE CLUB.

The Stereoscopic Exchange Club, established by the conductors of this journal, has, during two years and a half of its existence, been more extensive in its operations, and more successful than could possibly have been anticipated from a new and untried scheme. Many thousands of stereographs have changed hands through its agency, and very many of our readers are now in possession of an extensive and interesting collection of slides, which would have been unattainable by any other means. The members have secured by this method of private circulation a public for their productions, and have at the same time increased their variety of subjects for the stereoscope from tens, to hundreds or thousands. So far well: the club has more than fulfilled its mission.

There have arisen, however, from time to time, certain elements of dissatisfaction. There have been amongst the members some who, from ignorance, or from the absence of a delicate feeling of honour, have sent exchanges of very inferior quality to those they have received. The conditions of admission to the privileges of the club were that each member should send for our inspection an average specimen of his productions. In some few instances, not many, the specimens were so inferior that we could only counsel the applicant to be more careful, aim higher, or practise more—admission into the club with such powers being out of the question. We regret to say, however, that we have had some specimens sent to us from aggrieved members, who had received them in exchange, which were infinitely worse than the worst sent to us as average samples. Cases such as these, and some other circumstances, have led us to consider the suggestions of several correspondents, and to re-organize the club on a new basis, which will, we apprehend, effectually remove all sources of unfairness and consequent distisfaction, and lead to an extended system of advantageous exchange.

The plan we now propose for adoption, after a due consideration of all the suggestions made, and consultations with some of those most interested in the old club, will remove the responsibility from individuals to a committee of referees. Instead of exchanges taking place between individual members whose names are published, all pictures intended for exchange are to be forwarded to the secretary of the club. Once a month a committee of gentlemen, who have undertaken the duties of referees, will meet for the purpose of examining the pictures sent, and arranging the exchanges. Their aim will be to forward to each member pictures of equal merit with his own. The value of the pictures received by each member will, therefore, be in the direct ratio of the value of those he sends. Good photography will be exchanged for good photography; artistic, rare, interesting, and well-chosen subjects will be exchanged for subjects of the same calibre. On the other hand, bad, or slovenly photography, inartistic or common-place subjects, will meet with returns of the like quality; or if any be received transcending in badness all others, they will be returned as unsuitable for exchange. We are supposing an extreme case: we do not imagine that anything worthy of "that bad eminence" will ever be forwarded. But, in any case, justice will be done; every member will receive a fair equivalent for the pictures he sends. There will be, therefore, a strong incentive, to every one desirous of possessing a fine collection of photographs, to send good prints from his best negatives.

We may here mention an important consideration in connection with this part of the subject. In order to emphasise the idea that one good photograph is worth any number of bad or indifferent ones, any member having one thoroughly good picture, may, if he choose, send a dozen, a score, or a hundred copies of it for exchange, and receive copies of the best productions of every other member in return. It will not be necessary, therefore, that any gentleman wishing to avail himself of the advantages of this exchange, should have a large number of negatives. If he have one or two of pre-eminent excellence, he will contribute as usefully to the exchange, as those whose number is legion, and at the same time equally increase and improve his own collection. It will be desirable in such cases that the amount of excellence sufficient to justify large contributions of any one picture, be decided by the referees, and intimation conveyed by them to the contributor of such picture.

In order that the exchanges thus made may possess an educational value, in a photographic point of view, it is desirable that the rule rendering necessary a description of process, lens, aperture, light, &c., should be imperative. These particulars written on the back of the picture are apt to deface it when mounted, it is therefore resolved that such portion of the margin of the print as will be trimmed off in mounting, is the most suitable place for such information.

Hitherto the operations of the Exchange Club have been confined entirely to stereoscopic pictures. There is no reason whatever, why, under the new arrangements, the exchange of large pictures should not be as freely made. The production of stereoscopic pictures is ceasing to absorb the attention of photographers as exclusively as it once did. Many of those amateurs who tried their "'prentice hand" on stereoscopic manipulations, now aim at more ambitious results. The facilities for exchange will, we hope, encourage these efforts. The assurance that good pictures will be received in return for good pictures will induce many, we believe, to contribute. Some little care in packing will be necessary: a light roller of deal, an inch or less in diameter, is the best protection, and adds very little to the expense of transit in the book post. Nothing is more distressing than to see a good picture spoiled by folding in a letter, or other imperfect packing. It is a source of regret which we not unfrequently meet with. Correspondents send us charming views folded and cracked in a letter, and consequently ruined. Those only who reverence beautiful things can understand the exquisite sense of pain which the sight of photographic gems so maltreated causes us. In the Photographic Exchange Club, self-interest, if nothing else, will prevent careless packing, as the same packing, rollers, &c., sent by each person, will be received by him again.

Various plans have been discussed for meeting the trifling expenses contingent upon the new arrangements; and the method decided upon, we think, will satisfy all parties. It was most important to secure the gentlemen giving their services from any possible call upon their purses in such service; it was not less important that not a shadow of beneficial interest of a pecuniary kind should attach in any way to the club, or any one connected therewith. The plan of enclosing sufficient stamps to defray the expenses of postage and stationery, will, we think, meet both these positions.

As we have said, the responsibility involved in classifying the exchanges under the new arrangements, will be undertaken by three gentlemen. Some of our correspondents had suggested that we alone should undertake that duty: the position of sole umpire in such a case would be an invidious one for any individual, however thoroughly he might possess the confidence of the members. We have pleasure in stating therefore that we have secured the services of Mr. Sebastian Davis, one of the vice-presidents of the South London Photographic Society, and Mr. Frank Howard, treasurer of the same society, to act, in conjunction with ourselves, as referees. The latter gentleman will also act as secretary, and to him all pictures for exchange, and correspondence connected therewith, must be addressed.

The following are the rules to which members now desirous of joining the club are desired to conform :—

That the "Stereo Exchange Club" be reorganised under the title of the "Photographic Exchange Club," and that the object of the club be to exchange between its members, stereo, and other photographs.

That all gentlemen desirous of becoming members be requested to forward their names and addresses to the appointed secretary.

That the exchanges be made under the superintendence of three gentlemen, one of whom shall act as secretary, and the other two as referees.

That the exchanges be made monthly; all prints sent to the secretary for exchange during a given month shall be distributed during the following one.

That prints of fair average quality be alone admissible, and all inferior ones be rigorously excluded; that the exchanges will be regulated by the artistic as well as by photographic excellence, and that the decision of the referees shall be in all cases final.

It is desirable that all stereo prints be sent untrimmed and unmounted, and the right and left halves be carefully marked. Members sending mounted prints cannot be guaranteed mounted ones in return.

That members desirous of exchanging large pictures for stereo may do so; four stereographs being regarded as equivalent to a 10×8 picture, and other sizes in proportion.

That the names of the subjects, process, the lens and stop used, time of exposure and general conditions be legibly written upon a vacant margin of each photograph. Large prints should in all cases be sent on rollers, and otherwise carefully protected from injury; each roller sent will be used in returning the exchanged pictures.

To meet the necessary and incidental expenses, each set of stereoscopic prints and every communication sent to the secretary necessitating a reply, shall be accompanied with two penny postage stamps; and with each package of larger prints, stamps of a sufficient amount to cover the postage of properly packed exchanges.

That the duty of classifying the exchanges, or acting as referees, be undertaken by Messrs. Sebastian Davis, Frank Howard, and G. Wharton Simpson, and the duty of Honorary Secretary by Mr. Frank Howard, 12, Whittingham Villas, Studley Road, Stockwell, to whom all communications must be addressed.

The above regulations are to remain in force for one twelvemonth.

PHOTOGRAPHIC PORTRAITURE.*

On Likeness in Photographic Portraits.

It might be supposed that a portrait obtained by means of mechanical appliances would trace the features of the sitter literally; but such is not always the case, for many causes operate to deprive photographic portraits of that resemblance to the original, which, theoretically, they ought always to possess.

One of the most influential of these causes is, undoubtedly, too often inherent in the optical apparatus. On the one hand there is the cupidity of the photographer who strives to take his hundred or more portraits in one day "to make money;" on the other, there is the impatience of the sitter who can with great difficulty be persuaded to sit still for five seconds at a time; to meet these conditions there has been introduced into the operating-room lenses of very short focus, too short, in fact, the inevitable effect of which is to distort the face and figure in the images. It may be confidently asserted that photographic portraits can only be accurate when taken with lenses of long focus and of much larger diameter than the size of the proof is supposed generally to require. Thus it has happened that the *cartes de visite* portraits have been a kind of revelation, not only to the public, but also to a large number of operators, and their continued popularity may be well understood when their superior accuracy of likeness is taken into consideration.

Their value is best demonstrated when they are compared with the life-sized portraits affected by some operators.

Although the defect in likeness of a photographic portrait is due sometimes to the imperfection of the apparatus, want of skill and experience in the operator leads to the same result.

To assume that a likeness consists solely in the reproduction of the outlines of the model, and in the complete harmony of the several proportions constituting the whole,—is to degrade the photographic art to the rank of a purely mechanical operation. The sculptor makes his clay model, which his workmen, by means of measures and callipers, can imitate and reproduce with the most scrupulous accuracy; but this purely geometrical copy of the artist's conception lacks the last finishing touches of the hand of genius, the breath of inspiration that gives it artistic life. For, independently of the physical resemblance, there exists another, which may be termed the *moral*. It is that which by a gesture, a familiar attitude, by a certain something which is indefinable, enables us to recognise an acquaintance at a distance where the features are indistinguishable. It is this indefinable resemblance, that the photographic artist must be able to seize, and to arrive at it, he must carefully study his model, recognise the most accustomed play of countenance, and learn to appreciate everything which constitutes *individuality*. When the model is seated, or has taken the chosen attitude, usually a conventional one, it will be too late to think of his characteristic physiognomy, if it has not been carefully studied previously, or if the memory has not preserved a faithful impression of it.

Hence it is that the inartistic photographer, treating every model on a conventional system, entirely ignores or deforms the individuality of his sitter. To produce a good and faithful photographic portrait requires time and opportunity for studying the original; and this necessarily involves a greater expense than the public is willing to afford. And thus it happens that the majority of portraits are deficient in the elements of likeness that should render such works valuable.

On the Pose of the Model.—The first and most important condition of the *pose*, is to secure, during the whole sitting, the most complete and absolute immobility on the part of the sitter; for it should be well understood that the slightest movement of the body, or contraction of the visage, or the least change in expression, will render the most skilful and intelligent labours of the operator fruitless. Therefore, before everything, we must avoid giving a constrained attitude to the sitter, or one in any way difficult to maintain. Particular care must be given to the head-rest; and while securing its complete rigidity so as to afford complete immobility to the model, at the same time secure a simple, natural, graceful, and harmonious pose. Without this latter condition we can obtain neither a resemblance nor an agreeable picture; for, as already stated, a likeness is not only the exact reproduction of the features, but is also that of the *ensemble* of the whole person.

Especially must we avoid giving to our models tragic or extravagant attitudes which ignorant artists mistake for dignity, without reflecting that they suggest the idea of the model being taken while under the hands of a dentist or a lecturer upon electricity. Grace and dignity are far from being incompatible with simplicity, or even with a certain

* Continued from p. 472.

bonhommie. The head should be held level with the camera, without raising or depressing the chin too much. A portrait taken full face is only admissible for persons who are tall and thin. For all others, a three-quarter face, taken under such conditions of lighting as will be indicated hereafter, is preferable.

The eyes should be steadily directed on a fixed point, for example, on the aperture of the camera, and if it happens that the model is obliged to wink, it will immediately resume its gaze upon the point first selected. The arms should hang naturally, and without affectation, and if the artist considers it necessary to secure a particular attitude, there should always appear sufficient reason for adopting it, and in no case must the arms be allowed to project far from the body. A good disposal of the hands is, perhaps, one of the most serious difficulties the photographer, as well as the painter, has to encounter, for in this particular the artist has almost always to contend with his model. Foreshortening must be avoided; so also must the spreading out of the fingers like a fan. The stamp of elegance and distinction imparted by the hand is extremely difficult to acquire, and when it is possessed by the model is too frequently marred by affectation. Gloves generally produce a very bad effect when introduced into a photograph, and should always be avoided, if possible.

The carriage of the body also exercises a great influence upon the success of a portrait. Seldom, if ever, should the figure be taken in front, especially in the portraits of females; for this position is anything but favourable for showing the elegance of the figure. As a general rule, the body should be placed obliquely, the legs following the same inflexion, while the head should be turned in the opposite direction, showing three-fourths of the face. In no case should the legs project beyond the plane of the body, nor be crossed one over the other, nor straddling.

It is not always easy for the artist to obtain a rigorous observance of all the rules of a good pose from his model, such as have been indicated above. Every one has the pretension of fancying that he knows what attitude suits him best. The artist must not yield his better judgment to this conceit; for of what value is the appreciation or the judgment of a person who, after all, cannot judge artistically of the effect produced by his uncouth attitudes. The artist must consider only the judgment of those capable, by suitable cultivation, of estimating the artistic qualities of his works. In painting, the artist can improve upon his model's attitude if it be deficient in grace, but the photographer must never forget that his camera will copy literally the object presented to it, in all its deformity.

To overcome this perverse tendency of the model, the photographic artist must provide himself with an inexhaustible stock of patience, backed by politeness and amenity, which, however, must not exclude a certain amount of firmness derived from a consciousness of his talent. The photographer must exercise a real ascendency over his model, whom he must inspire with a certain confidence, and by a kind of magnetic influence communicate his own good humour to the physiognomy of his model. Without these conditions being fulfilled he will only obtain cold, formal, grimacing faces, which are the shame of photography, the despair of persons of taste, and the objects of a severe censure on the part of the critic and a discriminating public.

(To be continued.)

Scientific Gossip.

One of the most valuable works on chemistry, which it has been our good fortune to peruse, has just been published. It is the first part of Dr. Odling's long promised manual, which has for years been looked forward to in the hope of its proving a useful text-book for students in the unitary system of chemical notation, a system which is rapidly taking the place of the ordinary method of notation, but which has not hitherto had a worthy English exponent. The work before us in no way falls short of the expectation formed of it; indeed, from the great clearness and systematic manner in which every subject is arranged under appropriate heads, it would be difficult to find a book which is at the same time capable of affording such valuable information, at once to the youngest beginner, and to the experienced chemist. Those of our readers who possess a knowledge of general chemistry, as well as an acquaintance with the photographic branch of the science, will derive considerable information from a perusal of this volume; but as it is not to be expected that the majority of our readers are sufficiently good chemists to care about fathoming the mysteries expounded in Dr. Odling's volume, we will lay before them a few extracts referring to subjects of special interest to photographers, from which the exhaustive and masterly manner in which the different topics are discussed will be evident. Speaking of that very necessary body, water, we have the following complete account of its purification and properties from natural sources:—Water is not met with naturally in a state of absolute purity, but that produced by melting fresh water ice is often uncontaminated, save with minute traces of ammonia and carbonic acid. Pure water is obtained by distillation. The portion that first comes over should be rejected as liable to contain volatile impurities; a residual portion should not be driven over from the still, while the intermediate portion only should be collected for use. For special experiments, where absolute purity is required, this water should be twice redistilled: first with phosphoric acid, to hold back any volatile alkali; and then with hydrate of potassium or caustic lime to hold back any volatile acid.

Rain water collected in the neighbourhood of large towns, generally contains in addition to nitrate and carbonate of ammonium, sulphate of ammonium, organic and carbonaceous matters, and, it is said, traces of fixed alkaline chlorides, derived from the combustion of fuel going on within the town. Even in country districts, the first rain that falls after a drought, is contaminated with nitrate and carbonate of ammonium, and with organic matter; but the water of later rains is almost free from impurity. *River water* consists principally of rain water, which having fallen in more elevated districts, has gradually drained over and through the soil into lower districts, whence it travels downwards to the sea. The characters of river water are very variable, and depend chiefly upon the nature of the drainage area from which the river is supplied. Thames water, which is collected for the most part from an alluvial soil, contains about 18 grains of dissolved matter in a gallon, two-thirds of which consists of carbonate of calcium; the next most important constituent being sulphate of calcium and chloride of sodium. The Dee, of Aberdeen, which drains a granite district, contains in a gallon about 3 grains only of saline matter, consisting principally of carbonate of calcium, but also yielding marked quantities of potash salts, derived from the felspar of the granite. The Swansea rivers again, which drain a carboniferous district, abounding in pyrites, contain 3 grains and upwards per gallon of saline matter, consisting principally of sulphate of calcium. River water in the neighbourhood of towns is usually contaminated with sewage products from the artificial drainage of the towns. *Spring water* is derived from rain water, which having percolated the earth to a greater or less depth, is by natural or artificial means again brought to the surface. As a general rule, spring water contains a greater amount of dissolved matter than river water, on account of the greater quantity of earth that has been exposed to its solvent action. Spring water, also known as pump or well water, varies in composition, according to the nature of the strata from which it is obtained. *Lake water* corresponds in its characters with the river water of similar districts; lakes indeed being frequently mere expansions of, or reservoirs attached to, adjoining rivers. The supply, like that of river water, is derived chiefly from surface drainage, sometimes also from springs. Lakes are for the most part found in mountainous districts of the older formations, and the water of such lakes is very free from saline contamination. The Loch Katrine water, now supplied to Glasgow, contains only about 2½ grains of saline matter in a gallon. Domestic waters, whether obtained from rivers, springs, or lakes, are spoken of as hard or soft, according to the degree in which they possess the property of curdling soap. This curdling depends upon the formation of an insoluble compound by the union of the fatty acids of the soap with the lime or magnesia of the hard waters. The hardness, dependent upon the presence of sulphate of calcium, may be removed by the addition of carbonate of sodium to water; while that, dependent upon the presence of acid carbonate of calcium, may be removed by boiling, or by the addition of lime water. Either one of these processes effects a separation of the dissolved lime salt by precipitating neutral carbonate of lime *Sea water* has altogether a very uniform composition, although, indeed, the amounts of saline matter, yielded by different seas, are not precisely the same. Sea water has a specific gravity of about 1027, and contains, on the average, some 2,500 grains of dissolved matter in a gallon, including about 1,900 grains of common salt, and 400 grains of chloride and sulphate of magnesium. The quantity of salts in sea water is continually increasing; for the pure water, always evaporating or distilling from the sea, supplies the rain-fall of the earth's surface, and this, after scouring the soil over, or through which it flows, returns to the sea in the form of rivers charged with saline impurity. Hence the sea becomes the recipient of all soluble matters washed from the earth's crust. *Mineral waters* contain either some unusual constituent of water, or a great excess of some ordinary constituent. The principal varieties of mineral waters are the chalybeate or ferruginous, the sulphurretted or hepatic, and the saline.

Upon referring to that portion of the work which treats of the sulphur acids, we meet with the hyposulphites under a new name, *thiosulphates*. Hyposulphite of soda, which is here termed thiosulphate of sodium, is mentioned as follows:—The alkaline thiosulphates dissolve the halogen of salts of silver, forming double salts of a remarkable sweet taste, thus:—

$$Ag\,Cl + Na_2\,S_2\,O_3 = Na\,Cl + Ag\,Na\,S_2\,O_3$$

The thiosulphates or hyposulphites are much used for fixing photographic pictures, the thiosulphate of sodium being usually selected for the purpose. The photographic paper, or glass, uniformly coated with some silver compound, is exposed in the camera or press, and then immersed in a solution of the thiosulphate, which dissolves the silver away from those parts of the picture which have not been acted upon by light, and converts the silver compound that has been acted upon into unalterable sulphide of silver. This last statement is certainly very different from what is usually considered to be the fixing action, by our leading photographic chemists, of hyposulphite of soda.

It would be interesting to know the train of reasoning which led Dr. Odling to this conclusion. The theory of the action is described plainly enough, but we suspect that the experiments which should precede the theory were not such as would pass unchallenged in the laboratories of chemists who were at the same time experienced photographers.

A correspondent, W. M., has forwarded to us four pieces of glass for examination in the spectroscope. We append the results: No. 1 is of a light yellow colour, and allows both green and blue light to pass as well as yellow and red; it is, therefore, unsuitable for photographic purposes. No. 2 is somewhat darker than No. 1; it would be of no use in case bromide of silver were used, although it might be available for iodide of silver. No. 3 is an excellent glass, in fact, it is almost too good, as, along with the actinic rays, it cuts off a great quantity of light, which is useful for illuminating purposes. No. 4 is a light-coloured glass, nearly of the same degree of intensity as No. 2; it, however, possesses in a high degree that property of false dispersion to which we recently drew attention. In the spectroscope it is seen to cut off very perfectly all the rays more refrangible than *b*, and is, therefore, well adapted for employment in photographic laboratories.

INSTANTANEOUS PHOTOGRAPHY.

BY SAMUEL FRY.

Under the above heading it is proposed to describe the methods which I have employed to secure photographs of marine and atmospheric subjects, objects in motion, &c. I may premise there this will probably be found no invention of striking novelty, nothing calculated to effect a revolution in photography, but rather an accumulation into one complete system of manipulation, of a number of details, which though in the main already in the possession of photographers, have not in their entirety been hitherto recognised as constituting a reliable process. Some time since, I had occasion to publish in the columns of this paper, the process I had up to that time mostly employed, but though a great amount of success attended its practice, I found on commencing a series of experiments on the best means of obtaining maximum sensibility, during the early months of this year, that a fresh channel was open to me, from the improvements effected during the time which had elapsed since the conclusion of my earlier practice. I shall make a point of avoiding, as far as possible, any digression into mere experimental processes, even though such possess their share of interest for a large class. I shall simply describe in detail the arrangements I made to secure the highest sensibility, and at the same time obtain powerful and vigorous negatives. These pictures were for a commercial speculation, and therefore from the high standard to which such pictures have attained, and their being intended for printing transparencies, it was indispensable that the negatives should be absolutely faultless, so that the problem was to combine extreme sensibility with every quality that a fine negative should possess, vigour, half tone, atmosphere, perfect immunity from any, and all photographic shortcomings and bedevilments. It is commonly received as an axiom amongst photographers, that in proportion as the sensitiveness of the medium is increased, so also is the liability to irregularity of action, from the delicate balance being so easily disturbed, and without a doubt this idea is to some considerable extent justly founded. But I cannot but take this opportunity to say that I believe too much stress has been laid on it, and that amateurs have been deterred from attempting to produce instantaneous pictures from erroneous opinions respecting the difficulties to be encountered. But it will be worse than useless for any one to attempt rapid photography, unless he have previously acquired a very considerable manipulatory skill in ordinary collodion photography, as well as the gift of quick carrying out of the needful preparations.

It will be remarked that one great principle that I have held in view, has been to combine with complete efficiency of apparatus, as much portability as was consistent with the amount of work to be done. Another peculiarity is the method of simply developing the picture with iron whilst in the field, placing in a plate box, and fixing and intensifying at home, which need not be done until any convenient time. I describe this now in order to avoid any break in the continuity of the article on Development, Choice of Subject, &c. The camera which I had constructed for this purpose was fitted with a pair of double-combination stereoscopic lenses, and having a removable front, one of Mr. Dallmeyer's triplets could be adjusted; the latter lens covers a plate 7¼ by 4½, and includes about 65°. This form of picture is extremely pleasing, both from the large angle obtained and from its shape, which is admirably suited for sea and clouds, and for country landscape with hilly or wooded backgrounds. The exposure with this lens is, during summer weather, very nearly instantaneous; and with it may be seccued good cloud and general atmospheric effects, which many prefer to stereoscopic pictures. The range of focus of the camera is from 3 inches to $7\frac{1}{2}$, thus allowing full range for both lenses.

For developing out of doors, I had a box constructed 18 inches long, 13 high, and 13 wide, which held all my things—apparatus, chemicals, &c. &c.—and was so constructed that "when the door was opened" the contents were fully exposed to view without falling out, thus greatly facilitating its passage through a foreign custom house. It has been usual in all such contrivances that I have heard of, to inspect the development through a yellow glass, but for that I substituted a mask of gutta percha, edged with velvet, made to fit round the nose and forehead; this answered admirably, and I was able to develop out of doors with all the comfort of a laboratory.

The collodion I recommend is a thin bromo-iodized sample, which should have been mixed some considerable time, my own had, I believe, been iodized for many months. The results of using such a collodion are (begging Mr. Sutton's pardon for differing so widely from him), very exalted sensitiveness, great freedom from spots or blemishes, in consequence of the mixture having so thoroughly settled, and a certainty of the collodion being always in the same condition, which under the old system of using newly iodized collodion was very difficult to ensure. The silver I recommend for making the bath would be re-crystallised, at five shillings per ounce, this is dissolved 40 grains to the oz. of water, iodized as usual with about 3 grains of iodide of potassium for each pint of solution, filtered carefully, and then oxide of silver added to the clear solution, and agitated well at intervals for several hours. This effectually removes every trace of organic matter, and leaves the bath generally with an alkaline reaction, so that a fogged picture would result; but to prevent this I add to each quart one minim of strong nitric acid, and the immediate result of a trial of the bath will prove that (other conditions being right), the bath will yield, with rapid exposure, clean brilliant vigorous negatives, which give at the first operation of iron development, sufficient vigour to require but slight after intensifying. I strongly deprecate the system of adding ether or alcohol to a new bath, as it soon acquires more than enough, which sometimes causes markings on the plates.

The developer I recommend is 10 grains of iron, 30 minims of Beaufoy's acid, to an ounce of common water, the use of distilled water is an unnecessary complication, involving often much trouble, and answering no good purpose whatever. The only purpose in ordinary photography for which distilled water is required is the collodion bath, and for that it is not indispensable.

Critical Notices.

TURNER'S LIBER STUDIORUM. By Messrs. Cundall and Downes, Bond Street.

This is a series of reproductions from Turner's well known studies. The negatives were produced by Mr. Thurston Thompson from the original drawings in the museum at South Kensington. We may regard the publication of this series by the firm mentioned above, as the first-fruits of the protest made by ourselves and our contemporaries against the photographic monopoly at South Kensington. The printing and publication of this series was, instead of being produced at the museum, opened to public tender. Messrs. Cundall and Downes secured the contract, and have issued the work in a style of such excellence, and at a price so moderate, as to deserve the gratitude at once of artists, photographers, and connoisseurs; of all, indeed, interested in the possession of studies of such interest and value.

The number of drawings here included is thirty, the whole at the present time in the museum. If we remember rightly the total number included in the "Liber Studiorum" was considerably greater, if not double the number. The series before us constitutes, however, a very complete system of studies. The original drawings being in monochrome, chiefly sepia, the photographs which are exactly the same size, are absolutely perfect as fac-similes, and possess a value in this respect which infinitely transcends that of the best engravings of the same subjects. The printing has been conducted with great care and taste, so as to reproduce the exact tint of the originals.

Whatever may be said about the art claims of other applications of photography, here, at least, the most exclusive and jealous guardian of the recognized arts cannot gainsay the pre-eminence of photography. Not merely the drawing in its most literal accuracy, but the very touch of the master is reproduced with an unerring fidelity which the ablest copyist might in vain strive after with either pencil or graver. If not a fine art itself, it can reproduce and multiply works of fine art after a fashion, which it may defy the oldest and best of its challengers to equal or excel.

The value of Turner's "Liber Studiorum," as a series of studies, can scarcely be overestimated. Each picture is a masterpiece of composition and chiaroscuro, which landscape photographers would do well to study and emulate; and as each picture is, we believe, a study from nature, the subjects presented are entirely within the scope of photography to produce, most art students are already familiar with the value of such studies from the pencil of the greatest landscape painter of modern times, and will doubtless gladly avail themselves of the opportunity of possessing such perfect fac similes. They are of equal, if not of greater value to photographers, to whom we would earnestly recommend their appreciative study.

INSTANTANEOUS VIEWS OF PARIS. London: The Stereoscopic Company.

This is a second series of instantaneous street views of Paris, issued by the Stereoscopic Company. Excellent as were their former series, the present, in many respects, surpasses it. The most crowded thoroughfares of lively Paris are here most exquisitely rendered, with a perfection of definition and detail perfectly marvellous. Walking figures. running figures, falling figures, equestrian figures and vehicles, all caught in their acts without the slightest appearance of movement or imperfect definition. Here is a lad transfixed in the act of falling, flying forward, as something has tripped him up; he remains on the slide doomed neither to fall further nor rise again. Here we have unimpeachable evidence that two well-dressed Parisians were seen walking down the Boulevard Montmartre actually out of step, the right leg of the one and the left leg of the other being uplifted at the same moment. The majority of these pictures are entirely free from every trace of under exposure, and are brilliant, clear, sharp, bold, and delicate, some of them also possessing fine natural skies. They are also remarkably clean and free from blemish or manipulatory faults, furnishing fine examples altogether of what instantaneous pictures ought to be. Of the interest of the scenes it is unnecessary to speak. Life in Paris is almost a synonyme for all that is brilliant and gay, and these views are chosen from the busiest scenes of the gay metropolis.

INSTANTANEOUS SEA VIEWS. By J. Symonds, Ryde.

We cannot speak so highly of the pictures before us as of those we have just noticed. Whilst marine views present fewer difficulties than street scenes, the photography here is far inferior in quality. Many of these views on the solent are full of interest as far as the subjects are concerned, are also perfectly instantaneous and thoroughly well defined; there is a lack of brilliancy in some, and an absense of cleanness in others, which indicate either want of care or want of skill in the manipulator. These considerations apart, many of the pictures are well chosen and interesting photographs. One very fine and artistic picture entitled "Down by the sea is vignetted." This adds much to its charm as a picture, but militates against its effect as a stereograph. Stereoscopic pictures are intended to be actual presentments of nature as seen, sufficiently so to present an illusion to the eyes: this, of course, could never be the case with a vignetted picture, which in the stereoscope produces a most unsatisfactory effect. The view is, however, sufficiently fine as a picture to induce us to remove one-half fron its card and place it on another and larger mount. The chief thing Mr. Symonds, or his operator, has to study is greater care and cleanliuess, and to acquire a little more brilliancy in the negatives.

THE TOWER OF LONDON. By Dages and Harman, A. Gaudin, Sermon Lane, St. Paul's.

We have before seen isolated views of the Tower; but never until now an entire series, giving a complete view of this monument of old London. It is not too much to say that there is no building so fraught with historical associations of nterest as this old prison, slaughter-house, and tomb of so many nobles by birth or intellect, and the victims alike, whatever their merits, of a similar bloody fate. The ghosts of accomplished Raleigh, gentle Lady Jane Grey, ill-fated Mary, "false, fleeting, perjured Clarence," fair Anne Boleyn, and a troop of the other victims of her ruthless lord, who "spared no man in his anger, or woman in his lust," seem to flit by as we gaze in succession on the "Bloody Tower," the "Bowyer Tower," the "White Tower," the "Traitor's Tower," the "Constable Tower," the "Beauchamp Tower," and others, each marked by some dark memory. What a chapter on the virtues of kings is here suggested! We turn from these reflections to one more pleasant—the excellence of many of these pictures. Some are a little hard, but as a whole they are clean, brilliant photographs. Here is one which will possess historic value, a group of warders, or "beef-eaters," as they are known in common parlance, in the old historic dress, which has been, we believe, recently condemned, to be numbered amongst the things of the past. The series, which numbers between two aud three dozen, will, we apprehend, be in demand as a source of instruction as well as amusement. We may add, in answer to some inquiries, that these, as well as former series by the same artists, are published by A. Gaudin.

STEREOGRAPHIC VIEWS IN ITALY AND THE PYRENEES. By William Bircham, jun.

We have received from Mr. Bircham a dozen stereographs of scenery in Italy and in the Pyrenees, which far surpass the average of amateur photography. The views are well chosen, every gradation from the bold foreground, to the delicate mountainous distance, twelve or twenty miles off, is perfectly rendered, and added to this, in many instances, a fine sky, with delicate natural clouds. Most of the negatives appear to have been taken instantaneously, both clouds and running water preserving all their own characteristics, the clouds delicate and fleecy, the water transparent and in motion. Amongst those which especially please us are the "Tower of the Black Prince," "The Bay of Naples," the "Entrance to the Valley of Luz, from Argeles," and the "Marina and the Porta Felice, Palermo," all of which are decided gems of photographic scenery.

ON THE PHOTOGRAPHIC ACTION OF COLOUR.

BY J. CLARKE.*

The subject of the present paper is on the photogenic action of colour; a paper under the same title was read by me at the first meeting of the last session, but it would appear that the experiments there set forth were not entered into so minutely as could have been desired. Since then I have conducted further experiments in the same direction, and I now propose laying the result before this society, having promised to do so in a letter to our secretary (Mr. Wall), and which was read by him at the meeting following.

This paper will comprise a series of experiments on the photogenic action of colour on differently iodised collodions. The collodion used is that sold by Messrs. Horne and Thornthwaite, three separate ounces of which were iodised in the following manner, viz.:—

Collodion No. 1 with 4 grains of iodide potassium.
" No. 2 with 2 grains of iodide potassium.
and 2 grains of bromide potassium.
" No. 3 with 4 grains of bromide potassium.*

Now, as in my last experiments no attention was paid to the colouring matter employed, I hope in this to fully compensate for the deficiency, as every care has been taken to obtain the colouring substances in the greatest purity; the which, and the manner of employing them I shall now attempt to describe. A square of card-board was coloured with different bands in the following order, viz.:—1. Gamboge; 2. Yellow chrome; 3. Naples yellow; 4. Red chrome; 5. Vermilion; 6. Carmine; 7. Cobalt blue; 8. Ultramarine; and 9. Indigo. This was fixed against a wall, aud a photograph taken of it with plates prepared with each of the above collodions, sensitized in a 40-grain nitrate of silver bath, with an exposure of one minute each; the result of which will be seen in the following table:—

	Collodion No. 1.	Collodion No. 2.	Collodion No. 3.
1. Gamboge - - -	No action	No action	No action
2. Yellow chrome - -	No action	No action	No action
3. Naples yellow - -	Medium	Medium	Medium
4. Red chrome - - -	No action	No action	No action
5. Vermilion - - -	No action	No action	No action
6. Carmine - - - -	Slight	Slight	Slight
7. Cobalt blue - - -	Action strong	but not equal	to white
8. Ultramarine - - -	Action some-	what less than	cobalt
9. Indigo - - - - -	Slight	Slight	Slight

Thus it will be seen there is no difference perceptible in the action of each of these collodious; not that I conclude from this there is no real differeuce between the action of a bromide and an iodide, but I think it establishes the fact that there may be other causes to influence the action of colour than the presence or absence of a bromide in the collodion. Under some circumstances, however, the presence of a bromide may make an important difference in the resulting picture, but I do not think the action of colour would make any particular difference in the result; that is to say, I believe the action of any colour on the bromide of silver would differ little or nothing from the action of the same colour on the iodide of silver; of course these remarks only apply to the use of a bromide in a wet state, *i.e.* in collodion; but whether the same result would take place if silver plates were exposed to the vapours of iodine and bromine, and then submitted to the action of various collodions, I cannot say. In concluding these remarks, one or two thoughts suggest themselves; first, that objects in which the colours yellow and red predominate will have but little action on the sensitive film; at times, however, this is subject to a little modification, for instance, the action of some very bright reds is at times very great; the reason of this, at present, is not well understood, although it has frequently been observed by many experimentalists. The theory which I would advance in explanation, is, that possibly certain of these red colours possess the property of reflecting more of the non-visible actinic rays of the spectrum than other colours; this of course, remains to be proved.

The action of Naples yellow, marked No. 3 in the list, is somewhat great; but it is such a pale yellow, and reflects a considerable quantity of white light, therefore its actinic power is not so much to be wondered at; perhaps the selection of this colour was somewhat unfortunate, as I have never found any decidedly yellow colour give any marked action. The action of the blues are pretty uniform; the lighter the blue the greater the action invariably.

I have not touched on the action of any of the compound colours, as full justice could not be done in a short paper like the present; if, however, your committee should think fit to ask it of me, I shall be happy to conduct further experiments in that direction, as no doubt important modifications would accrue from the mixture of one colour with another.

British Association for the Advancement of Science.

BINOCULAR LUSTRE.

Sir David Brewster read a paper "On Binocular Lustre." He commenced by stating that some years ago it was observed by Professor Dove that when the right and left eye figures of a

* Read at the meeting of the South London Photographic Society, October 10.

* It is important to call the attention of the reader to the discussion on this paper in another column, from which it will be seen that there is reason to believe some error had been made in the experiments.

pyramid, or other mathematical solid, the one drawn on a white, and the other on a dark ground, were inserted in the stereoscope, the solid in relief appeared with a particular lustre. Professor Dove described the lustre as metallic, and in another place, where he described the diagrams as drawn with white lines on a black ground, and with black lines on a white ground, he stated that the pyramid in relief "appears lustrous as made of cyraphite." Other observers described the lustres differently some as resembling ground-glass, and others as like paper darkened with a black-lead pencil, while Professor Wood regarded it as "recalling the idea of highly polished glass." In order to explain this phenomena, Professor Dove remarked "that in every case where a surface appeared lustrous, there was always a transparent, or transparent-reflecting, stratum of much intensity, through which we see another body. It is therefore externally reflected light in combination with internally reflected or dispersed light, whose combined action produced the idea of lustre. This effect," he elsewhere added, "we see produced when many watch glasses are laid in a heap, or when a plate of transparent mica or talc, when heated red hot, is separated into multitudes of thin layers, each of which, of inconceivable thinness, is found to be highly transparent, while the entire plate assumes the lustre of a plate of silver." To these examples of lustre, produced by these plates, not in optical contact, or if in actual contact, having different reflective powers, were to be added the following: pearls, mother-of-pearl, pearl spar, and composite crystals of calcareous spar, and decomposed glass of all colours. The cause of these various kinds of lustre, and of that of metals, had always been well known, and when binocular lustre attracted the attention of philosophers, it was natural to ascribe it to the same cause. Professor Dove did this, and considered the dark surface in the one picture as the dispersed light, and the white surface as the regularly reflected light, the dark surface being seen through the white surface. This theory of binocular lustre, he had reason to believe, was not satisfactory. The phenomena was first observed by himself in 1843, under conditions of different forms than those under which it was subsequently seen in the stereoscope. Having adverted to a paper "On the Knowledge of Distance given by Binocular Vision," published by himself, in 1844, in the "Edinburgh Transactions," he said, that with his knowledge of the phenomena he could not adopt Professor Dove's explanation of the lustre seen in the stereoscope by the union of figures on dark and white, or differently-coloured surfaces. In order to test this explanation by other means, he combined faces that had no geometrical figures upon them, and he found that binocular lustre was not produced. This experiment seemed decisive of the question. He was led to infer from it that the lustre observed in the combination of right and left eye figures of solids, was not due to the rays from a dark surface passing through a lighter one to the eye, but to the effect of the eyes in combining the two stereoscopic figures, and to the dazzle occasioned by the alternating intensities of the two combined tints the impression of one of the tints sometimes disappearing and re-appearing. He referred to an article published by Professor Road, of Troy, on his (Sir David Brewster's) "Theory of Lustre," and which he disavowed, not having adopted any "theory of lustre." He had merely started an objection to Professor Dove's theory of binocular lustre, and an opinion regarding its cause; and as the simple experiment on which he founded that opinion had been made by others with a different result, he thought it right to re-examine the subject with the assistance of other ties than his own, and had obtained results which might be of use to those who were disposed to study the subject more elaborately. Binocular lustre was a species of lustre *sui generis*. It was a *physiological*, not a *physical* phenomenon, and had no relation whatever to those varieties of lustre which arose from the combination of lights reflected from the outer and inner services of luminated transparent, or translucent bodies. He assigned various causes for the physiological character of the phenomenon, and then added, "If binocular lustre arises from a physiological and not from a physical cause, we must look for this cause in the operations which take place in the eyes of the observer when binocular lustre is distinctly seen. These operations are of two kinds. First, in combining geometrical or other figures to represent solids whose parts are at different distances from the eye, the optic axes are in constant play, not only in varying the distance of their focus of conveyance, to unite similar points at different distances on the two diagrams, but in maintaining the unity of the picture by rapidly viewing every point of its surface. Secondly, when the two surfaces have different shades or colours, the retina of one eye is constantly losing and recovering the vision of one of them. Each optic nerve is conveying to the brain the sensations of a different tint or colour. The brain is therefore agitated sometimes with one of these sensations, and sometimes with the other, and sometimes with both of them combined; and it is, therefore, not an unreasonable conclusion that, in the dazzle produced by this struggle of flickering sensations, something like lustre may be produced. In studying the subject of lustre there are some facts deserving of attention. In a daguerreotype, for example, of two figures in black bronze, with a high metallic lustre, it is impossible, by looking at either of the pictures, to tell the materials of which they are made. No lustre is visible; but when the two equally shaded pictures are combined in the stereoscope, the lustre and true character of the material are instantly seen. Another instructive example is seen in the stereoscopic representations of a boy blowing a soap bubble. The lustre of the watery sphere is not visible in either of the two pictures, but when they are combined it is distinctly seen. In both these cases, and others of the same kind, tints of similar intensity are combined, and there is no ground for assuming that the two different surfaces combined appear at different distances, and that the one is seen through the other, as in Professor Dove's theory.

Mr. Cornelius Varley, of London, remarked that the mind could not attend to two things at once. Now, in the stereoscope, the eyes were forced to see two things, and whenever lustre was produced it was a species of dazzling which rendered the eye unsteady, and the mind was forced to see white and black alternately and unwillingly. Mr. Varley added that the first artist who attempted to teach his brother artists how to produce lustre was Hogarth.

In answer to a question, Sir David Brewster stated that he was not able to say that the instantaneous appearance of a solid could be obtained by the educated eye, after seeing the solid with both eyes, if one eye were shut the observer continued to see the solid for a certain time.

Proceedings of Societies.

South London Photographic Society.

The first meeting of this society, after the summer recess, was held in St. Peter's School, Walworth Road, on the evening of Thursday, October 10th. Sebastian Davis, Esq., one of the vice-presidents, in the chair.

The minutes of the preceding meeting having been read and confirmed:

The Chairman said: Gentlemen, In consequence of the absence of our president, I am unexpectedly called upon to make a few preliminary observations introductory to the proceedings of the session. We are re-assembled together for the purpose of exercising our thoughts, and communicating our experience, in connection with theoretical and practical photography. Although we are unable to boast of any remarkable or revolutionary modifications in our methods of proceeding, as having been devised during the recess, yet recent photographs bespeak a steady and general advance towards perfection. It will be within the recollection of our members, that the capabilities of light delineations as an artistic power constituted a prominent object of interest at the conclusion of the last session. Although this question was more immediately brought under our notice by the classification originally intended by Her Majesty's Commissioners for the 1862 Exhibition, yet we rejoice to find that its general consideration has not been devoid of direct and indirect interest. The classification finally adopted by the authorities, viz., that of giving a distinct department to photography in the forthcoming Exhibition, although not entirely realizing our hopes, is yet far more satisfactory than the original one. The fact is, that whilst upon the one hand we maintain that photography does afford to the artist the means of giving expression to his conceptions of the beautiful, we yet by no means desire to ignore the fact of the greater intimacy existing between the results of the scientific means used for their production, than the corresponding relationship between the materials employed, and the finished works of the painter or sculptor. Photography is as undoubtedly the offspring of science, as its higher productions are assuredly works of art. Instead of this intimate relationship affording an occasion of regret, it constitutes to my own mind a special and decided charm. Quite sure am I that if this relationship did not exist, photography would never have acquired that world-wide consideration that it at present commands. The man of science pursues photography, and in his endeavour to extend its capabilities, or to devise increased facilities for its successful exercise, is compelled to estimate his success by an art standard; the artist who employs photography as a medium for the expression of his thoughts, is compelled to depend for assistance and progress upon the researches of the man of science. This mutual dependence has the direct advantage of creating in the scientific mind a practical acquaintance with the detailed glories of Art, and of compelling the artistic capacity to familiarize itself somewhat with the innate poetry of science. That such mutual advantages have been prominently developed by the consideration of the theme in association with the Great Exhibition classification, prevents, I think, any regret at the occurrence of the discussion. The above observations naturally lead to a few remarks upon the future of photography, and more especially with reference to the proceedings of the South London Society. If we were called upon to express briefly an object that more than any other presses upon our immediate attention, it would be that of instantaneous photography. At the present time we may assert that the science affords every facility for the correct delineation of every kind of stationary object, either by the aid of the wet, or approved dry-plate processes. Instantaneous photography affords an excellent illustration of the present intimate association between the two leading features of our study to which I have referred. The great existing inpediment to the production of artistic pictures, arises from the comparative inability of obtaining sufficiently sensitive surfaces, and quick acting lenses to register moving scenes. How oftentimes do we ardently wish to record the momentary position of a passing event, a moving shadow, or an erratic cloud. What photographer has not felt an inward longing to depict the glorious medly of foreground foliage, or the momentary appearance of a distant view as seen between the interstices of some waving branches. It is true that the pictorial registration of colour may never be fixed by its own reflection, but we have no reason to doubt that the day may be not far distant when the moving scenes to which I have referred may be permanently delineated. There assuredly exists no greater barrier to the perfection of our results in a pictorial character than the blemishes which arise from our inability to correctly represent the moving objects of nature's scenes. I here, therefore, notice that a fair and promising field of investigation is at the present moment opened up to our scientific friends composing our experimental committee. They are hence presented with a labour that not only promises to yield an abundance of the pleasurable excitement incident to well conducted experimental researches, but one which, if it fail of its immediate object, will nevertheless be attended with many collateral advantages. If we can succeed in obtaining permanent records of passing scenes under ordinary circumstances of light, in inland situations, and with correct gradations of light and shade, we should give to our works a special beauty, that would successfully enable them to vie with those possessing the glorious charm of colour. I express a wish that our united labours of the session may contribute to the realization of our hopes, so that ere long photography may be capable of registering permanently every kind of form as momentarily delineated by the visual lens upon the sensitive tablet of the human eye.

Mr. C. Jabez Hughes then read a paper on "The International Exhibition of 1862: what are the arrangements made for representing Photography there?" (See page 485, in our last.)

Mr. Howard said, notwithstanding that he had in common, he presumed, with all present, given some attention to this subject, the unsatisfactory position in which photography stood in relation to the Exhibition, had never before been brought so forcibly to his mind. The proposal made to the parent society not having been accepted, he presumed the Commissioners would adhere to their first intention, and place photography in the mechanical department, amongst all kinds of manufactures. He presumed, also, that the period for making all applications for space having now expired, the only alternative that appeared to present itself as having the least chance of bettering their position would be by memorializing Her Majesty's Commissioners. Perhaps it was a matter in which professional photographers were more deeply concerned than amateurs, and any action should be taken by them. It seemed to him that if a sufficiently influential memorial were now forwarded to the Commissioners, they might be disposed to place the further management of the photographic department in the hands of a select body of gentlemen who might do it justice. Personally, he should be glad to aid any project which might be likely to improve the position of photography in the Exhibition.

Mr. Wall scarcely agreed with Mr. Howard that professional photographers should feel more interest in the question than amateurs. It unfortunately happened that the interest of professionals, in the matter, was often limited to £ s. d. This was not true of amateurs, whose exertions were rather governed by a genuine love of the art, and from their interest and effort he thought most was to be hoped.

Mr. Howard explained that he had only referred to the greater facilities which professional photographers possessed for contributing largely. Amateur photographers rarely possessed such a number of good negatives as professionals necessarily did.

Mr. G. Wharton Simpson wished to point out an error into which he conceived both Mr. Hughes and Mr. Howard had fallen, in stating that photography was to be thrust back into the purely mechanical companionship in which at first it appeared likely to be placed. He believed he had authority for stating that it was the intention of her Majesty's Commissioners to adhere to their decision as to a separate department for photography. That he believed was a decided point. The time had also expired in which applications for space could be made. The question now for consideration was, how to make the best of the separate department, and of the space already applied for, so as to secure for British photography a worthy representation. Had the parent society seen right to appoint a committee to take the direction of that department of the exhibition, the arrangements would probably have been such as would have satisfied photographers; but that opportunity was, unfortunately, passed. They, as a society, had approved of the protest which the parent society had made against what they conceived to be a degrading classification; but he did not believe one gentleman present had ever conceived the notion of absolutely declining to appoint a committee. If they could not entirely control, it would surely have been better to have availed themselves of the power in some measure to direct. At their last meeting he had the pleasure of moving a resolution approving of the steps taken by the parent society to obtain a better classification. Those gentlemen who remembered the terms of that resolution would recollect, that in it was an express clause, implying the possibility of having to accept the offer of a separate department, and suggesting that its acceptance be accompanied with a protest against being catalogued in the mechanical position. There was one consideration which perhaps they had somewhat overlooked in the first keenness of their mortification and annoyance at the humiliating classification in which they were placed. They regarded this classification as an affront passed on their art by the Commissioners. But the truth was, the Commissioners were not established as a tribunal to decide the position of photography. They merely accepted things as they found them. The recognized authorities in these matters—the Royal Academy for instance—did not admit photography to be a fine art. It was no part of the duty of her Majesty's Commissioners, therefore, to affirm that it was so. They did what was, perhaps, the most they could do; they said in effect to photographers, "Your position is as yet undefined; we will give you a separate department in which to prove your legitimate claims." Here then the challenge was thrown down to them; it was their duty to do their best and await the world's verdict. What they now required was a fair field: an assurance that their productions would receive justice in the separate department. They required the publication of such conditions as would stimulate photographers to do their very best with the space which would be allotted to them. So far as the matter stood, he had reason to believe all the arrangements were entrusted to one gentleman. He conceived the duties were too onerous, and the responsibility too great, for any one person, however able, to undertake, with comfort or satisfaction to himself, or photographers generally. Her Majesty's Commissioners were not in a position, however, to make further overtures, and it had been resolved therefore to ask this meeting to memorialize them, pointing out the immense importance of having a body of gentlemen, known and trusted by photographers, whose interest in the art would make them willingly undertake to cooperate with the Commissioners or the gentleman they had appointed, in securing the best possible management of the photographic department, and offering, if necessary, the aid of the society in carrying out such arrangements. With these views he had pleasure in moving that a memorial, which he would read (see p. 488 in our last), be presented by the South London Society to the Commissioners.

Mr. Howard was glad to learn that photography was still to have a separate department, where they could stand on their own merits. He had pleasure in seconding the adoption of the memorial just read.

The Chairman felt assured that every one present must feel the importance of having the management in proper hands. Nothing would be more lamentable than to see the walls covered with inferior pictures to the exclusion of good ones, a thing which by bad management might easily occur. He trusted that even now, by the appointment of a competent body of gentlemen, British photography might be able to maintain a creditable position.

The resolution for forwarding the memorial was then put to the meeting and carried unanimously.

Mr. Hughes expressed the pleasure and approbation he felt that such a memorial had been agreed to, and he thought that the society had been earning the gratitude of photographers generally in taking such a step. It was quite clear that somebody must move in such a matter. The thing could not be allowed to rest where it was without some effort. It was of the utmost importance that the Commissioners should be made aware of the views and feelings of photographers on the subject, and he trusted that other societies, now that the ice was broken, would also take action in the matter. Without some steps were taken, he saw nothing for the photographic contributions but to be handed over to the sappers and miners, of whose great photographic exploits at South Kensington, they heard so much. If they heard that the photographs, with an unlimited allowance of nails and red tape, were handed over to these sappers and miners to be tied up, who could they blame but themselves, if they had not taken steps to prevent such an issue? The Commissioners might very properly answer any protestation which might be made, when the thing was done, by informing photographers that they have done nothing but find fault, without making any effort to aid them. He was delighted to hear they were to have a separate department, and thought the Commissioners had, perhaps, done the most fair thing possible, under the circumstances, in thus affording an opportunity for photographers to prove their claims.

Mr. T. Clarke then read a paper on "The Photogenic Action of Colour." See p. 496.

The Chairman asked Mr. Clarke if he had rightly understood him that he had used for one of his experiments collodion containing bromide of potassium, in the proportion of 4 grains to the ounce, as that proportion was not soluble in alcohol of anything like the strength, say 60 over proof, generally used for collodion. Unless the alcohol was much diluted by absorbing moisture from the atmosphere, or some other cause, the amount of bromide of potassium soluble in it would not exceed two-thirds of a grain.

Mr. Clarke said he had used that proportion, but he was uncertain of the strength of the alcohol.

Mr. G. Wharton Simpson remarked that he thought there must be a singular mistake. Bromide of potassium was very insoluble in alcohol or ether, and the amount the Chairman had stated was the extreme quantity which could be dissolved in collodion made with solvents of the usual strength. If by any chance the alcohol became so much diluted as to dissolve the quantity named by Mr. Clarke, it would be utterly useless as a solvent for pyroxyline, and would, in fact, precipitate the cotton in collodion, to which it was added. Mr. Clarke's statement that a collodion containing a bromide only gave just the same results, with the same exposure, as a simply iodized collodion, and a bromo-iodized collodion, was also singularly opposed to general experience. He suggested to Mr. Clarke that possibly he had made some mistake using an iodide, instead of bromide of potassium. Under the circumstances, it would be satisfactory if Mr. Clarke would repeat his experiments with fresh chemicals.

Mr. Hughes said that the statements made by Mr. Clarke bore on one of the questions of vital interest to photographers, namely, the influence of bromides in collodion, and the effect of various colours upon them. He thought, however, Mr. Clarke must go over the whole of the experiments again, as there must be some mistake. It was impossible that the amount of bromide he had mentioned could be taken up, for if there were one salt used in collodion less soluble than any other, it was the bromide of potassium, and the statement that four grains had been dissolved, was so hostile to all experience, that they must ask for another and more careful repetition of the experiment. He called attention also to the fact, that in the plates experimented upon those colours described as having no action, really showed considerable reduction, the result produced by gamboge being nearly the same as indigo. There was, moreover, a general effect of fogging in the plates. In repeating the experiment, he would suggest the use of bromide of cadmium as being the most soluble bromide, and also the addition of some bands of black on the card as a starting point.

The Chairman stated that he believed some firms were in the habit of adding iodide of cadmium to what they called plain collodion, knowing that when it was afterwards treated with an alkaline iodizer the quality of the collodion would be improved by the presence of cadmium. Possibly all Mr. Clarke's results might have been vitiated from such a cause.

Mr. Howard suggested that in future experiments the greys and complementary colours, as well as primaries, should be tried, as it was with these rather than the primary colours, photographers had most frequently to deal.

Mr. Hughes thought that Mr. Clarke was right in trying the primary colours first, and thus endeavouring to establish first principles.

Mr. Simpson, in proposing the thanks of the meeting to Mr. Clarke, for the intention of his paper, suggested that he should begin again at the beginning. If possible, making his own collodion, assuring himself of the purity of his chemicals, and, for the purpose of assuring himself that any action taking place, was that of light from the various colours, and not spontaneous reduction or fogging, that some part of each plate be kept covered entirely, as this being quite clean and transparent would be a test of the chemical conditions. Possibly the Experimental Committee would think this subject sufficiently important to give some attention to it.

After some further conversation the subject dropped.

Two very fine photographs of interiors were presented to the society by Mr. V. Blanchard. Attention was also called to a fine solar camera picture, enlarged, by the same gentleman, and excellently coloured in oil by Mr. Wall. Both photograph and colouring received much admiration.

After the usual votes of thanks the meeting terminated.

Amateur Photographic Association.

We have received for publication the following report of a recent meeting of this Association:—

Committee.

The Most Noble the Marquis of Drogheda.
The Right Hon. The Earl of Uxbridge.
The Right Hon. The Viscount Ranelagh.
Sir Thomas Maryon Wilson, Bart.
Rev. William Thomson, D.D., Provost of Queen's College, Oxford, Chaplain in Ordinary to the Queen, &c., &c.
Matthew Marshall, Esq., Chief Cashier of the Bank of England.
Major Stuart Wortley.
James Glaisher, Esq., F.R.S., F.R.A.S., &c.
J. D. Llewellyn, Esq. F.R.S.
John Penn, Esq., F.R.S., &c.
George Shadbolt, Esq.

Honorary Secretary.—Mr. A. J. Melhuish.

Printers and Publishers.—Messrs McLean and Melhuish.

At a committee meeting of the above-named Association, held on the 30th ultimo, at 26, Haymarket, the Right Hon. the Earl of Caithness was duly elected a member of the committee.

Several practical details relating to the method of conducting the business of the Association, were discussed and arranged, and others proposed for future consideration. Numerous specimens of negatives, already sent in, were examined and approved, many receiving high commendation. Specimens of the proofs from some of the negatives, presumed to be a fair average of the whole, were also laid on the table. A report on the present state and future prospects of the Association was read by the Secretary and adopted by the meeting, as follows:—

It is with considerable satisfaction that I place before the committee the present state and future prospects of the Amateur Photographic Association, the scheme for which was first made known to the public in the middle of May last. Although hardly surprised, I felt much gratified at the outburst of approval with which it was received, and the very general and lively interest which it excited amongst photographic amateurs. From the first announcement of its formation to the present moment the list of members has steadily increased; this day, for instance, I have registered three new names, nor has its influence been confined to this country alone; but it has extended also to those on the European Continent, as well as to our most distant Colonies. This will be seen by the packets of letters now upon the table, including communications received from various localities in Europe, India, Canada, Antigua, Rio Janeiro, Cape of Good Hope, &c., which display an unanimity of sympathy with, and approval of, the objects of the Association, which is seldom witnessed. In fact, the sentiments expressed by correspondents, may be epitomized in these few words, which I extract from several of the letters before you, viz.:—

"I have much pleasure in joining the Association." "I cordially approve of the scheme." "I shall be glad to render it every assistance that is in my power." "I think the thanks of photographers are due to the gentlemen who have devoted their time and attention to the formation of so excellent an Association." "I believe it to be the very thing that was wanted."

The future prospects of this Association are no less satisfactory than its present condition. Although but a small per centage of the members have as yet sent in their negatives, those already received exceed four hundred, and whilst at least a multiple of that number may be safely calculated upon, should those who have yet to contribute do so, in anything like the same proportion, the number to be dealt with will be exceedingly large. Of the high quality of the negatives you will be able to judge from the several parcels now on the table before you, which have just been received, and from the proofs which I now exhibit, these being selected as a fair average sample from the whole of the negatives received up to the present time. I submit that these specimens demonstrate unmistakeably that we have amongst us photographers of whom the members generally may well be proud, and prove that the works of many amateurs are, to say the least, fully equal to those of their professional brethren. This Association, although little more than four months old, already numbers just one hundred and sixty members, and receives daily additions, so that we may fairly pronounce it to be a great success, being, to use the words of the prospectus, "An Exchange Club of the most extensive kind, a bond of union, and a medium of communication, such as no mere society, however excellent, can ever hope to offer, and which will give an interest and a stimulus to amateur photography, from which great results must flow."

Correspondence.

INTENSIFYING NEGATIVES.

Sir,—I see in your "Answers to Correspondents" one about intensifying negatives. I think the best of all methods is one I now use, viz., the application of a solution of the strength of about 2 per cent. of bichloride of platinum and subsequent washing. This leaves the proof, when dry, of a fine dark tone, and will be found excellent also for colouring positive transparencies for the stereoscope.—I am, sir, your most obedient servant, F. Maxwell Lyte.

Bagneres de Bigorre, October 7th, 1861.

PHOTOGRAPHIC FINE ART FOR THE MILLION

Sir,—The strong feeling in favour of photography that has lately been expressed by several of our most eminent painters who are actually employing it in the first delineation of their pictures, induces me to forward you a few remarks illustrative of the importance of this marvellous branch of the pictorial art. Every person at all accustomed to examine portraits, and compare them with the originals, knows well how rare it is to find a good likeness of the sitter. And though it is common enough to see a well painted picture, yet even this degree of perfection is usually acquired by a sacrifice of the truthfulness of the portrait; so that when we turn from one of the best productions of the pencil, and compare it with a photograph from the same sitter, we are struck with the marvellous stride that has been made by changing the laboured production of the easel, for the instantaneous result of the sunbeam. By this process the very perfection of God's own image is at once placed before us, and even distant scenery is copied with a perfection of perspective and accuracy of detail, far beyond any efforts of the human pencil.

Even the science of optics has received an impulse from photography that the most sanguine could hardly have anticipated, and it has been more cultivated for the improvement of the "camera" during the last ten years than it had previously been since the discovery of the telescope.

But the best feelings of the human heart have been greatly fostered by the labours of the photographic artist. The poorest artisan is now enabled to ornament his humble home with life-like resemblances of his family, who thus remain as durable mementos, whilst the cherished objects of his love are too frequently removed from his domestic circle; so that the result has been a higher patronage of portraiture than existed in Florence in the days of Lorenzo de Medici. Then there was but one patron, but now they are found in every street. Their name is "legion," and photographic portraiture is the best feature of the fine arts for the million that the ingenuity of man has yet devised. It has in this sense swept away many of the illiberal distinctions of rank and wealth, so that the poor man who possesses but a few shillings, can command as perfect a life-like portrait of his wife or child as Sir Thomas Lawrence painted for the most distinguished sovereigns of Europe.

With thanks for the large amount of useful information contained in your photographic miscellany, I am, yours faithfully, C. F. Partington.

Cornwall Crescent, Camden Town.

THE PISTOLGRAPH, MOONLIGHT PICTURES, &c.

Dear Sir,—The Photographic News of last Friday has just come to hand, containing your very excellent description of the pistolgraph. Permit me, however, to demur to the following:—

"For all objects beyond a distance of about twenty-five feet the pistolgraph requires no focussing, everything beyond that distance to infinity appearing in equal focus."

In practice, I find, when the instrument is charged with an excited plate, and it is desirable to pistolgraph, a group of unconscious equestrians advancing or receding at a sharp trot—yet as it might not be practicable "to put the group in appearance" where the focus was indexed, viz., at 25 feet, a quick definite turn of the plate-holder on its axis, to the right or left, at the instant of exposure, would give the required sharpness to the moving object at any distance between "the 25 feet" and infinity, Believe me, dear sir, Yours truly, Thomas Skaife.

P.S.—Apropos of Gaudin *versus* Breese on "moonshine." Some three years ago, whilst casting about for a suitable lens for my pistol camera, I espied a boy playing with one of Sir David Brewster's grooved spheres, commonly called a Codington lens, of about a quarter of an inch focus from back surface. Having prevailed upon the young philosopher to lend it to me, I at once set about testing the photographic capabilities of this little objective. Being satisfied as to its competency to deal with solar objects, I wished to ascertain how it might be trusted with lunar ones. So taking advantage of a full moon, I tripoded the little camarette, charged with a wet collodion plate, in face of my dwelling for half an hour; then developed with pyrogallic: the result was a tolerably distinct view of my house, with every window facing the moon clearly defined. After this, a back view was tried. The house being between the moon and the camera, a 20 minutes' exposure gave a sharp clear outline of the house against the moon-illumined sky. But it is not expected that M. Gaudin is such a *goube-mouche* as is *un tel mi Lord Anglais* to swallow such "*audacious moonshine.*"

TAXES, FOR PHOTOGRAPHY.—SUNDAY PHOTOGRAPHY, ETC.

SIR,—The "photographic nuisance" has, it seems, taken quite a different aspect from what it had at first. From the fact of a ruffianly fellow and his equally ruffianly "doorsman" illtreating a troublesome customer, and the consequent question of the best method of getting rid of such "dens," which we soon should see accomplished if we could but get rid of the "doorsman," or touter, as, without their assistance, the public would never be induced to enter such places at all,—from a consideration of this matter, the subject has been warped into a sweeping denunciation of sixpenny likenesses and Sunday photography, though where the necessary connexion exists between such a fact and such a consideration must have puzzled many of your readers. Now, sir, it is really too bad that all who take sixpenny portraits should be classed in the same category with the ruffian before alluded to. And as to the Sunday question, it is a purely religious one, into which I am very reluctant to enter; but I may say, that although neither I nor my brother (with whom I am associated) take portraits on Sundays, yet it is not because we consider it sinful to do so, but because we defer to the wishes of our neighbours. And I know that there are many *Christians* who hold the belief that Sunday is not the true Biblical Sabbath, but that Saturday is the proper day; and one at least of Mr. Swatridge's rivals (I know) holds the same opinion. And I should think the fate of the numerous "Sabbath Observance" Bills of late ought to convince the most bigotted, that the spirit of the age will not allow any further interference in that direction with the liberty of conscience.

Then, as to the proposal to tax or "*protect*" photography, I am sure that every well-wisher to the *art* as such, or as a profession, would be sorry to see it fettered in any way—its infancy having been sufficiently crippled, without now endeavouring to drown its more mature growth—but indeed after your able exposition of the fallacy of such a plan in the leader of this week's NEWS, there needs no further arguments from me to show the utter inapplicability and inexpediency of such a measure.

The proposal to found a college—from which to issue diplomas, deserves consideration; but it would be necessary that the examinations should include the *practical manipulations* of the art, as well as the theory, or the scheme would be not only useless, but positively mischievous. It is very easy to send specimens to the editor of a journal like the NEWS, in order to entrap the editor into remarks, so that *garbled* extracts from them may be used as puffs in country newspapers, but it is quite another thing to work before the practised eyes of veteran photographers.

I trust that you will excuse the length of these remarks; but I feel that it is but right that some one ought to vindicate the character of those who, like myself, are not above taking a sixpenny portrait.—I am, sir, your obedient servant, J. WALTER.

[Whilst willingly affording opportunity for the expression of opinion amongst every class of the photographic fraternity, we cannot admit personalities into our columns. Our correspondent will see, therefore, why we have omitted some passages from his letter.—ED.]

DEAR SIR,—Having read Mr. Swatridge's first letter on the subject of taxation of photographers generally, my first impulse was to write to you at once, denouncing the system as unjust and wrong in itself; for, as you say, in these days of free trade, our attention ought to be turned to abolishing all taxes of a similar nature, that have withstood the brunt of time up to the present day. Thinking that the affair might blow over, and no further notice taken of it, I was prevented doing so, but seeing another letter from him this week upon the same subject, and also one from another correspondent, a sense of duty to myself and others now compels me to drop you a few lines on the same vexed question. It is, in my opinion, wrong to suppose for a moment that by compelling photographers to take out a license for carrying on their calling, we should in any way put a stop to, or even mitigate, the nuisance so much talked of; for I believe that one half of the owners of these dens are much better able to pay for the said license than men of greater respectability and talent. The reason is obvious; they do not stick at the means by which they are to get the money, and I know from sad experience that there are men of worth and respectability, aye, some little talent too, who would I am afraid be utterly unable to do any such thing. I think it an oversight on the part of Mr. Swatridge to think that because he is so circumstanced as to be able to pay such a tax, there are no deserving men who are not. I know that there are such; that the manner in which they conduct their business, as also the quality of work done, there is no doubt about. I have likewise known, and still know, men who have nothing but their unprincipled ways and bad work to recommend them; yet such men get on, and, I repeat, better than some that are more deserving, and were the tax to be imposed on quality of work, so far as mere show goes, they would not be behind hand at the time of show, but that would not make them less unprincipled or better workmen themselves. I quite concur with him in his opinion that the public generally are but poor judges at present in matters photographic, for they will often go, not only the lower class, but those who think otherwise of themselves, to some low place, allured with the idea that they are about to have something cheap, and positively pay more for the same style of article, though of very inferior quality, than they would pay at once for a good article at a respectable place, but I think the public taste in such matters will soon improve, and then merit may fare better.

With regard to the proposition of W. B. N., I consider it much more feasible, and to display a much greater sense of justice, but I for one object to the system in all its phases, and am extremely glad to see that you take up the matter in the same spirit. Allowing you to make what use you may please of this, and apologising for troubling you, I am, sir, yours very truly, J. LEES.

SUNDAY PHOTOGRAPHY.

THE LONDON PHOTOGRAPHIC SUNDAY CLOSING ASSOCIATION.

SIR,—I am delighted to see this movement set on foot at last. To judge by appearances it is, perhaps, not quite safe; but the beginning of this association is very promising. Scarcely had the notice of its formation been placarded in this neighbourhood when it was evident that the thing was meant to be carried out. I could mention several studios, my master's amongst the number, *which were closed last Sunday for the first time since they were opened.* Until now, the photographer (whether master or man) has toiled day after day. The relaxation of a holiday, or day of rest, has been denied him. Good Friday, Christmas Day, and other like occasions, have been no boon to him. But I rejoice to see the movement taken up with spirit, and from amongst our own ranks, and I wait anxiously to see what its development will be. Not that I fear the result, for I am certain that the portrait making Sundays are numbered in this city, but the movement deserves, and must have, the sympathy and help of all who have suffered under the old system, like, sir, your obedient servant, A. DOORSMAN.

Photographic Notes and Queries.

THE RESIN PROCESS.

SIR,—Have any of your correspondents tried in the resin, or gum process, gum guaiacum. I coated a collodion plate with an alcohol solution of the gum after exciting, and exposed and proceeded to develop, and found my picture visible all over the plate and very intense. I added some to some uniodized collodion with the same results; a weak developer fully brought out the picture. S.

P.S.—The revolving front and one lens camera has been in use some time, I used one invented by M. Marriott, Esq., and manufactured by Messrs. Murray and Heath five years ago, for taking stereo views four on one plate.

Talk in the Studio.

Sunday Photography.—We call the attention of our readers to the following copy of a placard, which has during the last week been freely posted about the metropolis. We announced in our last, that an organization for the suppression of this nuisance was in course of formation, and shall from time to time keep them advised of its progress in suppressing this disgrace to the art:—"The London Photographic Sunday closing Association. Notice! this association is now being formed, under distinguished patronage. Public meetings will be shortly convened in all parts of the metropolis, with a view of making the movement universal! Notices of these meetings will be widely circulated; and it is hoped that the public will aid the photographic profession in its efforts to abate one of the greatest nuisances of the present day, viz., Sunday Portrait Traffic."

Poisoning by Cyanide.—On Tuesday an inquest was held on the body of Mr. John Baker, a gunmaker, who died from the effects of poison. He had desired his wife one night after retiring, to go into another room and bring him a certain bottle of medicine containing black draught. As soon as he had drank some he discovered that it was the wrong bottle, and exclaimed that he had taken aquafortis. He called immediately for mustard and water, which he drank. Medical attendance was at once procured, but very shortly the unfortunate man died. The bottle when examined was found to contain a weak solution of cyanide of potassium. Another illustration of the danger of having such deadly poisons standing amongst medicines or other articles of domestic use.

India-rubber Cement.—A cement called *marine glue* from not being affected by water, is made as follows:—Take one pound of india-rubber, cut it into small pieces and dissolve it in about four gallons of coal-tar naphtha, the mixture being well stirred for some time, till perfect solution has taken place. After ten or twelve days, when the liquid has acquired the consistence of cream, two parts, by weight, of shellac are added to one of the liquid. This mixture is put into an iron vessel having a discharge pipe at the bottom, and heat applied, the whole being kept well stirred. The liquid which flows out of the pipe is spread upon slabs and preserved in the form of plates. When required for use, it is heated in an iron pot to about 248° Fah., and applied hot with a brush.

Photography in the Reformatory.—A novel and interesting application of the art is now in daily use at the famous Mettray colony, near Tours, which is the first and most celebrated reformatory established in France for young convicts. Every urchin brought to this house of correction has his portrait taken the moment he sets foot in it, and another is made on the day of his leaving. The first represents the rags, dirt, and misery, the physical and moral degradation, the prematurely careworn features, the scowling, cowering, timid, uneasy, and withal ferocious look of the born thief. The second shows the same individual transformed by the magic of judicious discipline, which includes physical comfort and kind treatment. His dress is now clean and neat, and his countenance is redolent of health, contentment, benevolence, and energy. Philosophy had never in any age, a grander subject for contemplation than two such pictures. More than one of the English reformatories adopt a similarly interesting record of the good they effect.

The Tannin Process.—A correspondent sends us the following:—"To photographers who smoke: a piece of cotton wool steept in a solution of tannin, and put into the bowl of a pipe, as a plug, will remedy all the nausea and hot flavour of the tobacco."

Silver from Waste Solutions.—*The American Journal of Photography* says:—"We are informed that in one of the city galleries, during the past two months, there has been saved from the waste developing solutions *twenty-three ounces* of metallic silver. This fact establishes two other important and curious facts, viz.:—That a certain New York gallery in time of war has been doing a very good business, and that silver can be practically saved from the developer. We have believed and taught, for a long time, that at least seventy-five per cent. of silver, purchased by photographers, is needlessly wasted. There is no waste so easily prevented as that of the developer.

To Correspondents.

J. W.—The most certain way to prevent pictures from curling up or warping after mounting, is to damp the opposite side of the card, so that both sides shall contract equally in drying. As this is troublesome where there are many to be done, the next best plan is to avoid using much moisture in whatever is used for causing the prints to adhere. India rubber solution will answer the purpose, as will also, freshly made Scotch glue. These will cause less tendency to curling than paste.

Nautilus.—The black precipitate in your toning solution is probably a little reduced gold. The tones of those you send are good; we shall be glad to see the others.

West Countryman.—We have not used the iodide or bromide of magnesium ourselves, nor do we see any especial advantage in their use. We have recently seen some very fine pictures produced with a collodion containing them, but we think the gentleman who produced them would have obtained just the same results with any other of the usual bases for his iodide and bromide. We believe the magnesium iodide is less stable than many others. Most photographic chemists will probably keep it; Mr. Thomas makes a feature of it. We hope shortly to be able to publish the experience of an able photographer as to its use. Your suggestion regarding the society might be useful, but we fear there is no chance of such a thing being carried out.

Roselli.—To re-crystallise nitrate of silver, dissolve it by the aid of heat, in twice its weight of distilled water, then evaporate the solution with gentle heat over a water bath to half its bulk. Now set aside the vessel to cool, keeping it lightly covered to preserve from dust, &c. In twelve hours you will find fine crystals formed; pour away the remaining solution into another vessel, and leave the crystals to dry. This first crop of crystals use for purposes requiring great purity; those obtained from the remainder of the solution will do for common purposes, such as printing. 2. A good iodizing solution for collodion may be made as follows: 8 grains of iodide of sodium, 8 grains of iodide of cadmium, 2 grains of bromide of cadmium, in one ounce of alcohol 60° over proof. Add 2 drachms of this solution to 6 drachms of plain collodion.

H. Jones.—The yellow precipitate is carbonate of silver, arising from the addition of carbonate of soda in excess. It will be re-dissolved on adding nitric acid. Always neutralise with oxide of silver, which, combining with the free nitric acid, forms nitrate of silver. The proportion of nitric acid to be added to the baths in the formula you enclosed is very great; 4 drops to each ounce of solution are decidedly more than necessary. The strength of silver is, you observe, very great, 48 grains to the ounce. That is the reason for adding so much free acid, as without plenty of free acid strong baths are difficult to work without stains. A 40-grain bath with 2 drops of nitric acid will give fine results for positives.

W. May.—You will see an examination of your glass in the proper place. We shall be glad to learn something of the preparation of the samples which are suitable.

E. C. J.—We received your former prints as well as two now. At that time we scarcely saw how you could best avail yourself of the exchange system as it then stood, as postage with India would have been expensive. We waited, therefore, until the new arrangements then in contemplation were decided upon, which you will see in another page, is now done, and you can, by forwarding prints, with the requisite amount of postage, to the secretary, receive all the benefits of the Exchange Club. We are obliged by your prints, which are full of interest. We shall always have pleasure in receiving specimens of progress.

A. Stevens.—The description of Mr. Fox Talbot's process of photographic engraving, given in our "Dictionary of Photography," in No. 98, was necessarily only an epitome of the process. You will find full particulars, as stated in the specification, on page 73 of our first volume. We have not had experience in the matter ourselves. 2. The photographic ink is not now manufactured, we imagine. It simply consisted of nitrate of silver and nitrate of potash.

Wax Process.—Marion and Co. used to keep excellent iodized waxed paper; but since the demand is so small, we are uncertain whether it is kept at all now. You will probably procure the Canson paper of Mr. Saudford.

Ebonite.—We beg to inform some correspondents who have enquired on the subject, that Mr. Atkinson, of Liverpool, is agent for the photographic goods of Ebonite, manufactured by Silver and Co.

J. L.—We have seen excellent card portraits produced by the No. 1 B. lenses you name; and know many of our best artists who use them. They cover well, give excellent definition, and are very rapid. We do not know of any lenses better suited for the work except the No. 2 B of the same maker. These latter have produced by far the finest card portraits we have seen, the definition over every part of a standing figure being exquisite, and the action, in a good light often instantaneous. In securing rapidity of action in lenses there should be no loss in definition: as a general rule lenses giving the best definition are the most rapid lenses. There is, of course, a great advantage in these lenses in point of rapidity over ordinary half-plate lenses, but it is difficult to state the proportion without actual trial. We have not tried chloric acid in the silver bath. The addition of oxide of silver would form chlorate of silver. Since you find acetic acid so satisfactory, it would be folly to make any change.

N.—We are disposed to think the damage in the corner of the negative, which renders vignetting imperative, a fortunate circumstance, as unquestionably the pictures gains by vignetting, and we cannot conceive that any other form would be so beautiful. We should be very glad indeed to receive the series of specimens referred to, indicating the capabilities of weak baths; and any information regarding the mode of use to secure the best results. We will examine the prints received at leisure, and report upon them in our next. There was an error in the figures in our last answer, as the "*avoirdupois*" appended shows. "437·5 grains" should have been written for "480 grains." The confusion existing in the standard of weights and measures sadly wants rectifying. For an exact statement in of the strength of silver solution, see table in our number for May 2, of this year. "N" indicates a wish to preserve his incognito. We have been under the impression, how gained we scarcely know, that we were perfectly familiar with the letters which follow the initial, and at once examined the broken seal for the "red hand" we expected to find. The seal was, however, too much broken to afford us any satisfaction.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 164.—*October* 25, 1861.

PHOTOGRAPHY AND THE EXHIBITION OF 1862.

The consideration, so important to photographers, as to whose direction the photographic department of the forthcoming International Exhibition, shall be committed, remains, at present, undecided In a recent announcement of the names of sub-committees for undertaking the various departments, no allusion was made to photography, from which, we conclude, Her Majesty's Commissioners are still undecided on the matter. A fortnight ago we published a memorial which had been adopted at the South London Society, and forwarded to the Commissioners. The object of this memorial was to impress upon the Commissioners the importance of a speedy decision on this subject, and of entrusting the matter to capable men. We should be very glad, unless some decision is announced very shortly, if other societies would take action in the matter. Her Majesty's Commissioners must not be led to believe that English photographers are indifferent about a question of such vital importance.

We are glad to perceive that there are some signs of a better mind, in regard to this subject, in the management of the Photographic Society. The change is odd enough, and oddly enough expressed, implying, as it does, that the real nature of the offer made by the Commissioners, was not understood until now. A leader in the recently issued number of the Society's *Journal*, says :—

"We have received several communications from correspondents on the subject of what is called the recent concession of the Commissioners of the International Exhibition to photographers. It appears that a separate department is now to be given for the arrangement of photographs. If this is the case, we can only say that it is a great pity that this was not vouchsafed sooner, as it would have saved a great amount of trouble. We think that under these circumstances it would be very desirable for the Council to meet to consider what steps ought to be taken in the matter, as it is very important that competent persons should be appointed to help and guide the Commissioners in their labours. We urge this simply from the unanimity shown in the number of communications forwarded to us on the subject since the recent change in the aspect of affairs."

That this separate department should be accepted is what we have been steadily urging for months past, and we are glad to believe that, though late, our advice has, at length, produced some effect. We have availed ourselves of every opportunity of impressing the fact that since a separate department was to be granted, some "competent persons should be appointed to help and guide the Commissioners in their labours." The very phrase we have so often used was, that it was better to "guide," if we could not entirely control.

Singularly enough, however, the matter is treated as though this separate department was a "recent concession." "It appears that a separate department is *now* to be given," is the phrase used, and, it is added, "we can only say that it is a great pity that this was not vouchsafed sooner, &c." Now we must on behalf of the Commissioners, and in defence of our own consistency in urging the acceptance of a separate department during so many months past, point out the disingenuousness of this assumption of a recent concession. In the Society's *Journal* for June, we find a letter, dated May 16th, from Mr. Sandford, secretary to the Commissioners, in which, after pointing out that there was nothing in the decisions of the Commissioners which would prevent photographs being placed in juxta-position with engravings, &c., he distinctly adds that special space will be allotted to photography, and it is the hope of the Commissioners to "assemble in one apartment all the photographic apparatus and photography, so as to illustrate fully the state of photography as practised throughout the world at the present time." That is upwards of five months ago. So soon as this offer was made, we saw that especial advantages would attend such a separate department for the photography of the world, and we have persistently urged this opinion ever since. We are, as we have observed, glad to observe a change of opinion in our contemporary, the organ of the society; but it is too bad to assume that it is in consideration of some recent concession. How far the council can now act in the matter we cannot say, and how much less dignified any advances they may now make will be, than if the offer of the Commissioners had been accepted at the time, we leave others to determine. If any steps they can now take, and which can be accepted by her Majesty's Commissioners, will tend to the advantage of photographers and tend to the improvement of the photographic department of the Exhibition we shall be very glad. All our aim in this matter in what we have done in these pages, and elsewhere, has had but this object: we wish to see British photography fully, fairly, and honourably represented in an exhibition comprising the industry and art of all the world. Photography as now practised is essentially an English art. It derived its being from two Englishmen, Fox Talbot and Scott Archer. It is an English pursuit; there is not such an extensive amateur photographic public in any country in the world. And this is an English exhibition. If, therefore, British photography be imperfectly or shabbily represented, or if the exhibition be ill managed, the brand of disgrace will be a deep and lasting one.

We may here add that we have reason to know that the applications for space which arrived from photographers at the last moment are such as to justify the hope that if the contributions are in like ratio, and the department be well managed, a much more satisfactory result will be obtained than at one time seemed probable. How important a proper management of the department will be to its success, may be gleaned from the information as to the mode in which such things will be arranged in other departments, given in the following extract from a morning contemporary :—

"Excluding an incredible number of utterly absurd applications, which have been thrown aside altogether, the total amount of space demanded by intending exhibitors in the United Kingdom is 1,200,000 square feet, or just six times as much as the Commissioners have at their bestowal. It will be the duty of the several committees to bring down these figures to a manageable point. The metropolitan and local committees will have to look after the interests of their constituents, and to take care that particular branches of industry, or localities, are duly represented. The class committees will attend to matters of more national import, and will provide suitable room for chemical products, minerals, naval and military objects, general mechanism, and the fine arts. In short, the aggregate allotment of space which the commissioners have decided upon will be divided among forty classes, and subdivided among individual exhibitors, by a process of inter-consultation with the different committees."

It is quite clear that the necessity for a competent committee to manage the photographic department is a pressing one; and every photographer must begin to feel the importance of knowing the conditions which are to guide him in his preparations.

VALEDICTORY.

It is always a source of regret to us to have to chronicle the retirement from the ranks of any of the veterans of the photographic art. It is not, however, quite surprising that such retirements must occasionally take place. Photography is an engrossing pursuit, and requires for its satisfactory and successful practice, no half-hearted attention. Those who love it best will, when they cannot accord to it this full attention, be most likely to resign it altogether, unwilling to pursue the art unless they can give it the time necessary to success. We have now to take leave of the Rev. J. Lawson Sisson, a gentleman whose name has been honourably connected with photography from the very first. His waxed paper process has yielded some of the finest results which have ever been produced in that direction; and various of his suggestions, in connection with dry photography and other departments of the art, have been of considerable value. He writes to us briefly, saying, "I have ceased to be a photographer, finding that the art demands more time than I have now at my disposal." We may perhaps be pardoned for adding another quotation from his letter on a subject regarding which, although we often receive kind communications, we are, in our columns, always silent; but an expression of opinion from one so long known in connection with the art, and now leaving it, may excuse a breach of our custom. He adds, "I cannot, however, avoid saying that the News is, as far as I have been able to judge, the very best photographic journal published; and I most heartily wish it every success." Mr. Sisson is to us, personally, entirely unknown; but we, in common with all photographers interested in the early progress of the art, necessarily respect his opinion as well as his labours; and in wishing him a kindly farewell and good speed in his more immediate duties, we but give expression, we apprehend, to the feelings of photographers at large.

CORRECTING NITRATE BATHS.

A correspondent recently detailed in our columns such a history of "The Nitrate Bath and its Troubles," as might well nigh frighten the tyro just stepping on to the threshold of photography from proceeding any further in what might appear such a bewildering and perilous enterprise. The case there described was no doubt an extreme one, and not often met with, we hope, at least in such a virulent form. Every photographer has, however, at times met with more or less difficulty in the management of his bath, and we now propose, very briefly, to consider two or three of the remedies which have been recently suggested by practical photographers.

We cannot for a moment pretend to solve all the difficulties which we have heard described by first-class photographers as occurring in their own practice. There are some we have heard described which seem to defy conjecture as to either the cause or the remedy, and can only be attributed to the presence of some unknown impurity in the silver. We have never had the misfortune, in our own practice, to meet with a bath which we could not easily correct. Instead of misfortune we might have said good fortune, for our duties give us an interest in cases of failure or irregular action, similar to that felt by the pathologist in cases of morbid anatomy. Abnormal reactions are always interesting, as failures are stepping-stones to success. In our own practice, however, the disordered state of our baths has generally yielded to very simple treatment. Since the appearance of the "Nitrate bath and its troubles," several correspondents have written to suggest remedies. One experienced photographer writes to say, "I beg to forward a remedy which I have used now for three years, and have never known to fail. I can put any number of plates in my bath, sometimes as many as a hundred a day, and never fear its being out of order." The panacea on which this correspondent relies, and his practice demands that it should be a reliance, is "pouring into the bath a little (about a teaspoonful) of the cyanide fixing solution, two or three times a week, when the day's work is done. The bath will yield splendid results next day. If this should be neglected, and the plates should fog, I can then add the cyanide, and the fog will clear off at once."

He adds "I don't mean this remedy for a bath that is not sufficiently acid, but for one that fogs from what I suppose to be the excess of iodide set free from the collodion plate. The fog that is caused by alkalinity shows itself in marks up and down the collodion plate, whichever way it is placed in the bath. But the fog to which I allude is that which shows the picture with a veil completely over it. The picture develops apparently all right, but upon fixing it appears under a cloud," The first bath in which our correspondent tried this remedy, he states, appeared like "pea-soup," but on addition of the cyanide solution became at once clear, and worked perfectly.

Another correspondent suggests as an infallible remedy, and one which has been sold as a "trade secret," for high sums, the addition of a small quantity of chloride of gold. Another, following the same principle, suggests the addition of a solution of chloride of sodium for the same purpose.

It is quite possible that under certain conditions of the bath each of these applications might, on known principles, prove beneficial. The addition of cyanide would produce cyanide of silver, which being, comparatively speaking, an insoluble salt, would be precipitated. It is a well-known property of insoluble precipitates, so formed, that they carry with them, frequently, other foreign matter, with which a solution may be supersaturated. Iodide of silver in excess would thus be carried down, and possibly organic matter also. The nitric acid liberated on the formation of cyanide of silver, combining with the potassium, and forming nitrate of potash, would leave the bath in the same condition as regards acidity as before. Whether any trace of cyanide of silver might remain in solution, and how it might affect the working of the bath, we cannot say.

Regarding the action of chloride of gold or sodium, they would act in a similar manner by forming an insoluble precipitate, but in the case of the first a trace of nitric acid would be liberated, which might in some cases be an additional advantage. Some years ago Mr. F. Eliot proposed the precipitation of the iodide of silver from solutions of nitrate of silver by means of citric acid. Two grains of citric acid in solution were to be added to each ounce of silver solution. If a precipitate did not immediately fall, ammonia was to be added, a drop at a time, until a white precipitate of citrate of silver fell down, taking with it the iodide of silver, and probably some other accumulated impurities. The bath was then to be tested for acidity or alkalinity, and corrected accordingly. If alkaline from the additional excess of ammonia, a little nitric acid would be needed; if acid either from the nitric acid liberated on the formation of citrate of silver, or from a trace of citric acid in solution, oxide of silver might be added. This process was proposed with especial reference to removing iodide from baths which had been used for exciting collodion plates, in order to appropriate the solution to printing purposes.

Our own practice, in dealing with old baths surcharged with iodide of silver and organic matter, has been, first, to dilute the solution to half its bulk with distilled water, which, by weakening the solution, aided the precipitation of excess of iodide. We have then added oxide of silver, and after thorough agitation, exposed the solution in an open shallow vessel to the sun, or in a warm place, for some hours. This has effected the double purpose of blackening and reducing any organic matter, and evaporating excess of ether. Fresh nitrate of silver, sufficient to produce the proper strength, has then been added, and a plate tried. In some cases the bath works well at once; if not, a trace of nitric acid is added, and all goes well. We have never found this method to fail: it is a little troublesome, but only requires performing perhaps once in six or twelve months with a bath in constant use.

New baths, which refuse to work satisfactorily without the addition of an immoderate amount of acid, we simply treat with the oxide of silver, expose to light, filter, and again acidify. This is always sufficient. We know there are cases where this treatment fails, as we have heard of them from reliable photographers; but we have never met with them. As we have said before, such cases, we apprehend, are due to some radical impurity in the nitrate of silver.

PHOTOGRAPHIC PORTRAITURE.*

On the Dress of the Sitter.—With respect to *photogenic effect*, the dress of the model may be considered under two aspects: the nature and arrangement of the material of which it is composed, and its various colours. We shall afterwards consider the artistic effect required to be produced.

It is well known that woollen stuffs, and all those which present a dull surface, whatever be their colour, are very difficult to photograph. It is, therefore, preferable to adopt vestments composed of lustrous tissues and where the nature of the textile material, or rather the arrangement of the threads, produces brilliant reflections. Silks appear to merit the preference; but velvet, so rich in effect in all its shades, is far from being represented in all its advantages by a photographic apparatus. Glossy, lustrous, and shot fabrics, whether of silk, cotton, or wool, are the most suitable to be reproduced photographically.

As to the colours of the drapery, as a general rule, those must be avoided which form too violent a contrast with the complexion of the model. It is necessary to make a careful study of the manner in which photography translates the various colours, for a hue which appears a very dark one to our light will very frequently appear white in the picture, and *vicé versâ*.

Thus, blue, lilac, violet, and purple, however, dark they may appear, are always produced as light tones in photography, while yellow, green, and red, however light in tone, always appear more or less black. This difference in the translation of colour must be carefully studied and constantly kept in mind by the photographer.

With reference to the artistic effects which the artist must endeavour to obtain from the vestments and drapery, it has already been remarked that too strong a contrast between the colour of the vestments and the complexion must be avoided; we may add that too great a contrast between the colours of the vestments themselves must be equally avoided, so that the *ensemble* of the photographic image be harmonious and agreeable to the eye. Consequently, plaids of large patterns and large figures in all patterns, must be avoided, as tending to confuse the eye and distract it from the principal object, which is the face. To abuse the marvellous facility presented by photography, of representing the minutest details, is to misunderstand the office of the true artist, whose pure taste will always lead him to sacrifice details and accessories to the principal object.

Lighting the Model.—The rules to be followed in illuminating the model are very simple, and yet they exercise a great influence upon the success of the portrait. The principal condition to be considered is that of avoiding *zenithal* light, that is, such as falls perpendicularly upon the head of the model, producing opaque shadows under the eye-brows, nose, and chin, and on all the salient parts of the figure generally. A horizontal light, arriving directly in front of the model, or on one side of it, produces the best effects; still the light must be modified by screens and curtains, so that both sides of the face are not equally lighted. We naturally reserve the greatest effects of light for the side that exhibits most of the face, but we must also avoid depriving the other side wholly of light, otherwise, we obtain only a picture half light and dark, with a harsh effect of chiaroscuro most intolerable to the artistic eye.

Too strong a light greatly fatigues and annoys the sitter, and completely neutralizes the harmonious effect sought by the true artist. It is much the best to subdue all excessive illumination, even if it leads to longer exposure, provided it be not pushed to unreasonable limits. Portraits taken in the open air, except with a due appliance of screens, to modify the light are generally very inartistic.

Under certain cirumstances, such as when the operator has to work in an atelier situated in the narrow streets of a city, a glass-house, will be indispensable; in other circumstances, where there is large window with clear uninterrupted view, the best effects may be obtained by a judicious arrangement of reflecting surfaces.

* Concluded from p. 493.

PHOTOGRAPHIC CHEMICALS:

Their Manufacture, Adulterations, and Analysis.

Sulphuric acid—(coutinued).—One remarkable property of sulphuric acid still remains to be noticed, and that is, the action which at a certain degree of dilution, it exerts upon cellulose or vegetable fibre. It has long been known that this acid, under certain conditions, modified vegetable fibre, and after numerous experiments, Mr. Gaine discovered that when paper is submitted to the action of two parts of concentrated sulphuric acid (sp. gr. 1·854, or thereabouts) with one part of water, for no longer time than is taken up in drawing it through the liquid, it is immediately converted into a strong, tough, skin-like material. All trace of the acid must be instantly removed by careful washing in water. If the strength of the acid greatly exceeds or falls short of these limits, the paper is either charred, or else converted into dextrine, and the same conversion into dextrine also ensues if the paper be allowed to remain in the sulphuric acid many minutes after the change in its texture has been effected. In a little more than a second of time, a piece of porous and feeble, unsized paper, is thus converted into the parchment paper; a substance so strong that, as stated by Mr. Barlow, in his lecture on this subject, delivered before the Royal Institution, in 1857, a ring seven-eighths of an inch in width, and weighing no more than 23 grains, sustained a weight of 92 pounds; a strip of parchment of the same dimensions supporting about 56 pounds. Though, like animal parchment, it absorbs water, water does not percolate through it. Though paper contracts in dimensions by this process of conversion into parchment paper, it receives no appreciable increase of weight, thus showing, that no sulphuric acid is either mechanically retained by, or chemically combined with it. It has also been ascertained, by analysis, that no trace of sulphur exists in the parchment paper. This fact of the paper retaining its chemical identity constitutes an important distinction between it and gun-paper, or cotton. Unlike these substances, it is neither electric, nor is it soluble, in ether and alcohol. Unlike common paper, it is not disintegrated by water, and, unlike common parchment, it is not decomposed by heat and moisture. The strength of this substance, and its indestructibility by water, have caused it to be applied to many uses. It, to some extent, replaces vellum in book-binding, it furnishes material for legal documents, such as policies of insurance, &c., and it is likely, before long, to take the place of ordinary paper, in school and other books, which are exposed to constant wear. One great advantage of this method of treatment, consists in it being applicable to paper after it has been printed on, either from type, or in intaglio, as no part of the impression is obliterated by the process, the lines, owing to the contraction of the paper, being considerably sharpened, and a fine gloss being communicated to the surface.

At the time above mentioned, several experiments were tried by Mr. Crookes, on the applicability to photography of this method of modifying paper. It is well known to chemists, that, in many cases, a strong acid exerts a less energetic action upon bodies, than the same acid diluted; and it was found by this experimentalist, that the darkened portions of a positive paper photograph resisted the action as well as the paper itself. As several advantages are likely to arise from a more general use of this method amongst experimental photographers, we briefly give the best method of proceeding with the manipulation. Mix, in a sound stoneware jug, 4 fluid ounces of water with 8 fluid ounces of oil of vitriol of commerce, taking care to add the water to the acid, and stirring constantly all the time. To avoid danger of spilling the mixture owing to the jug cracking with the heat evolved when the acid and water mix, it should be placed in a basin of sufficient capacity to hold the contents. When the acid is cold, pour it out into a good porcelain dish, and by the side of this have two large pans of water. The photograph, which must be on unalbumenized paper, and quite dry, is now to be taken by one corner, and laid, picture-side downwards, upon the acid, taking care to avoid air-bubbles; then instantly lift it up, and lay the plain side on the liquid; this will be very easy with the assistance of a glass rod, as the acid has a tendency to cause the paper to curl outwards, contrary to the action of water. The paper must now be left in the acid, for a space of time varying from one or two seconds to as many minutes, according to the absorbent quality of the paper—unsized English paper requiring a very short time, whilst more absorbent paper requires longer immersion. When properly soaked, quickly remove the prints and transfer them to the first pan of plain water, where they may be shaken about rapidly to remove the excess of acid on the surface. The second pan of water should have a little ammonia in it, so as to give it a decided alkaline reaction, and as soon as the surface acid is removed from the print it is to be immersed in this alkaline bath, and there left for a short time, in order to make sure that no acid remains unneutralised. As soon as this bath shows the slightest tendency to redden blue litmus paper, a few drops of ammonia must be added, and the whole well mixed; for if even the slightest traces of unneutralised acid remain in the paper after removal from this bath, the picture will soon be destroyed. Photographers must not, however, forget that long soaking in ammonia is prejudicial to the half-tones of the picture, and the excess of alkali must therefore be but small. After being removed from this alkaline bath the sheets will require to be washed two or three times in clean water, and they can then be dried in any convenient way. When dry they will have an uneven. crumpled appearance, which can be removed either by rolling or by careful mounting whilst slightly damp. The result will be, in several respects, worth the photographers' careful attention and experiment. The colour and tints of the picture, even in the most delicate half-tones, remain perfectly intact, whilst the powerful, yet uniform contraction of the paper, adds considerably to the sharpness; the paper is moreover suddenly gifted with such great strength that not only will it bear very rough handling during the washing process, without the possibility of accidental tearing, but, owing to the horn-like character of the surface, it will at any time, even when dry and mounted, bear hard rubbing with soap and water and a wet cloth without any abrasion of the surface, if it is dirty enough to render such a mode of cleaning advantageous. Moreover, the surface (of an unalbumenized print) assumes a peculiar glossy appearance, giving a richer finish to the picture without the glare which is objected to in albumenized prints.

Another important advantage was suggested by the author at that time; it was stated as very probable that pictures so treated would be found to be less liable to fade than they otherwise are, and an experiment was described in which a rapidly fading print was treated in this way with marked advantage. We understand that Mr. Crookes has continued these experiments, and, as nearly five years have elapsed since the first prints were treated in this way, the results will throw considerable light upon this obscure subject,

We hope in a short time to be able to communicate Mr. Crookes' results to our readers.

INSTANTANEOUS PHOTOGRAPHY.

By Samuel Fry.*

The chemicals necessary to be carried on a trip for instantaneous pictures, are neither bulky nor numerous, and are simply (besides the bath and collodion) protosulphate of iron, acetic acid, hypo, pure iodine, pyrogallic acid, and iodide of potassium. Instead of the separate bottles of iodine, and iodide of potassium, may be carried a 4-oz. bottle of a mixture of 4 grains pure iodine, 4 grains iodide of potassium, and 4 oz. of common water.

I strongly recommend stereoscopic instantaneous pictures to be taken on plates $7\frac{1}{4}$ by $4\frac{1}{2}$, thus allowing a large margin, and permitting the best part of the picture to be selected, whether at the top or bottom of the plate. For obtaining instantaneous effects, I have already described a shutter inside the camera, opening from the top downward. This shutter is the same width as the diameter of the lens, and does not, therefore, occupy the whole of the space of the interior, and has not been found in practice to cause a dust, as has been suggested, and thus give rise to blemishes and spots on the plate. It is indispensable that the shutter open from the top first, as, though the whole time of exposure may not exceed one-tenth of a second, yet, even of this almost inappreciably small period, the foreground has, by this arrangement, a larger share. I was drawn to this conclusion by the result of a number of experiments I tried on the best form of dark shutters. By means of some thin boards and india-rubber string, various arrangements of spring shutters are easily made for experimental purposes. At the first glance it seems that, to fulfil all purposes desired, there should be two shutters, separating in the centre, which is thus exposed first; but though this is probably the way to obtain the most rapid movements, yet it will be found in practice that the foreground is constantly under-exposed, and the middle distance over-done; and I therefore still incline to my original system of an internal shutter opening downwards, in order to give most exposure where most is required. In photographing water and sky with shipping, great advantage is gained by being at an elevation of ten or fifteen feet, such as on a pier or break-water; for not only is a more natural vivid effect obtained by the rendering of varying shades, representing with great truthfulness many of the ever-changing tints of the surface, but we thus obtain reflections of clouds, and shipping in the water, in an enhanced degree, each contributing its quota of beauty and interest to the picture.

A deservedly favourite point with instantaneous photographers, is to include in their pictures steamers under full steam, but to accomplish this successfully requires some management, both to obtain the best photograph, and also the best artistic effect; it will soon be discovered that far better effects are obtained by selecting, if possible, a steamer when receding, than when approaching; the heavy swell from the paddles, the long, clearly-indicated lines of the steamer's course, the rounded stern of the vessel, the foreshortened side view, give exquisite details, and all within the scope of an experienced photographer.

My ordinary practice for development is to bring out the picture, as far it will come, with a 10-grain developer of iron; I then wash the plate with two ounces of water, and at once put it in a plate box without unnecessary exposure to daylight. In the evening, at leisure, I fix the pictures with hyposulphite of soda, and after thorough washing allow it to dry spontaneously. In this condition, and before intensifying, they may be brought home, and made deeper in colour at any convenient period afterwards. My usual proceeding for intensifying, is to first run a line round the plate one-eighth of an inch in width, of Hughes' black varnish, this dries at once, and prevents the film splitting off during

* Continued from page 495.

subsequent wetting. When this varnish is dry, wet the plate thoroughly with common water, in a room partly darkened; next pour off and on for one minute the mixture of 1 grain iodine, 1 grain iodide potassium, and 1 ounce of water; a slight darkening of the picture will be perceptible after washing this preparation carefully off, and then follow up at once with pyrogallic acid, 3 grains to the ounce, and with acetic acid as usual; before pouring on add a few drops of 30-grain solution of silver, kept for that purpose only. Intensity will be immediately acquired, and must be arrested when far enough, or hardness may result.

During the present year a large number of very fine instantaneous pictures have been taken, and the public taste has been thereby greatly improved, the once popular views of "cities of the dead," as those dull, deserted looking productions have been justly called, which have till recently satisfied the public, will no longer go down. Mr. England's exquisite views of Paris, with their great and charming variety of figures, horses, and vehicles, all in motion, give a life, an individuality, to the scenes, such as we can never again part with. Henceforth no views, whether of streets, sea, or country life, can pass without containing at least some of the attributes of instantaneity. This change will be of equal benefit to photographers and purchasers, for at the same time that a more severe censorship is exercised by the latter, the standard of excellence is so much elevated thereby, that both amateur and professional photographers are incited to fresh conquests, the apparently impossible gradually opens before them in unexpected clearness, and they find that they must either rapidly advance with the vanguard of progress, or be left hopelessly behind in well-deserved obscurity.

The one point, however, to which my previous remarks might not appear to apply at first sight, is the practice of portrait photography; yet in no branch of our art is instantaneity so desirable, or so difficult to obtain under ordinary circumstances. Truly, with recent appliances, the average exposure is reduced to, say, 5 seconds, and in the prime of the year, 2 or 3 seconds, in a good light, and this advance, it must be conceded, is of inestimable value as giving an approximation to "the consummation most devoutly to be desired"—instantaneous portraits—but we must never rest until we obtain either such sensitiveness of materials, or such power of reducing agents, as to be able to obtain our portraits in the "twinkling of an eye." Then, indeed, may we reasonably look for a large increase of knowledge of art principles; then, instead of being as it now is, a mere block, dead to all other ideas than the stern necessity of sitting still, the human face divine may beam with intelligence, show that there are brains inside the skull, and instead of being perpetuated with an expression seen at no other time than when "sitting for a portrait," may be taken during the flow of ordinary conversation, with an easy, natural individuality stamped on every feature and limb, that we are now but little acquainted with.

The promulgation of instantaneous photographs at a moderate price, will do more to inculcate a true artistic feeling amongst photographers than anything written on the subject; no words can convey to the mind anything like an idea of the perfect reflex of nature which they display. It seems hard to conceive how any intelligent, unprejudiced person can deny to such productions the right to enter the charmed circle of works of art, but we must remember that photography is very young, that in any branch of science, a long tedious study of first principles is needed before a certificate of competency is granted, that though many photographers may have relinquished in its favour, the "farm, and the merchandize," yet that if all work together with a will, it is impossible but that the art shall be placed in its proper position—an honourable niche in the temple of the arts.

EXPERIMENTS IN THE MANUFACTURE OF COLLODION.

Mr. W. S. Thompson communicates to the *Journal of Maryland College* the following record of experiments in the manufacture of collodion:—

"For the purpose of testing the solubility of the cotton in menstrua of ether and alcohol mixed in various proportions, I prepared a series of three, which I will designate by numbers, as follows:—

No. 1.	
Ether, parts, by measure	5
Alcohol, do.	1
No. 2.	
Ether, parts, by measure	4
Alcohol, do.	1
No. 3.	
Ether, parts, by measure	3
Alcohol, do.	1

FIRST EXPERIMENT.

"Sixty grains of carded cotton were immersed in the following mixture:—Nitric acid (sp. gr. 1·41), 1 fluid ounce; sulphuric acid (commercial), 1 fluid ounce. Having mixed the acids in a shallow porcelain dish, the temperature rose to 90° Fah., and fell to 80° Fah., when the cotton was immersed. At the expiration of ten minutes, the cotton was thoroughly washed with water, and dried at a low temperature. One part of this cotton, and 150 parts, by weight, of menstruum, No. 1, formed a very thick collodion, leaving a small quantity of undissolved sediment. With menstruum No. 2, in the same proportion, it also formed a good collodion, with about the same amount of sediment as in No. 1. With menstruum No. 3, in the same proportion, it formed a thick collodion, with scarcely a trace of sediment, or undissolved cotton.

SECOND EXPERIMENT.

"Sixty grains of cotton were immersed in the acid mixture in the same proportion as in the first experiment, in a deep porcelain mortar. Upon mixing the acids, the temperature rose to 105° Fah., and fell to 95° upon immersing the cotton. By this experiment, a more soluble cotton was formed than in the first experiment; but menstruum No. 3 proved to be the best solvent.

THIRD EXPERIMENT.

"This experiment was made with double the amount of material used in the preceding, in the same mortar. Upon mixing the acids, the temperature rose to 120° Fah., and fell to 110° Fah., when the cotton was immersed. The resulting cotton was entirely soluble in menstruum No. 3, but with Nos. 1 and 2, leaving a small quantity of sediment.

"From the foregoing experiments, I infer that an elevated temperature, say from 110° to 130° Fah., is favourable to the formation of a very soluble collodion cotton, and that a menstruum containing a large proportion of alcohol is the best solvent."

[Mr. Thompson appears to be considerably behind the age in his information on this subject. It has long been decided in this country that a moderately high temperature is favourable to the manufacture of a perfectly soluble cotton. Instead of placing the maximum temperature, desirable for the best results, at 130°, he might, with advantage, have placed it at 150°. In regard to the proportion of alcohol, instead of regarding one part to three, of ether, as a high proportion, he might, with advantage, have used them in equal parts.—Ed.]

M. BLANQUART-EVRARD'S METHOD OF PRINTING BY DEVELOPMENT.

Most photographers have seen and admired some of the exquisite developed prints which some years ago used to be sent out by M. Blanquart-Evrard. The method of producing them was a secret, the whole details never having transpired. Mr. Sutton, who at the time was working in conjunction with M. Blanquart-Evrard, has recently published the whole process, which until now he has not felt at liberty to do. We were examining some of the prints only a few days ago, and were more than ever impressed with the conviction that they possess a degree of richness, depth, and delicacy, rarely, if ever, found in a sun print on albumenized paper. The use of albumenized paper seems to have become a necessity: it certainly affords facilities for obtaining more of the detail in the negative, than plain paper. But there can be little doubt that it is an unpleasant necessity, and that only a conventional and acquired taste could tolerate a work of art, resembling an engraving, covered with a vulgar glaze. The developing process in question is described in the "Notes" as follows:—

"The paper was first steeped for some hours in a solution containing

Water	1 oz.
Gelatine	4 grs.
Iodide of potassium	4 grs.
Bromide of potassium	1 gr.

and then hung up to dry. It was Canson paper, and the iodide gave it a pale red colour.

"The next operation was to submit it to the vapour of hydrochloric acid. A mixture of two parts acid to one part water was put into a large leaden tray, having a close fitting top, with a large square hole cut in it, an inch smaller each way than the sheet of paper. The paper was then laid over the hole and exposed to the acid fumes, with a plate of glass laid on the top to keep it down.

"The exposure to the acid fumes lasted a quarter of an hour; after which the paper was removed, and immediately laid upon the surface of the nitrate bath, where it remained for another quarter of an hour. There were several nitrate baths in use at the same time, and the room in which the papers were excited, had an immense round stove in the centre, which made the room as hot as the Palm House at Kew Gardens. When the paper was removed from the nitrate bath, the excess of solution was blotted off, and it was hung before the stove to dry. The pieces of blotting paper were dried also, and used again for a similar purpose, until they became completely saturated with silver, and then they were burnt, and the silver extracted from the ashes.

"As soon as the sensitive paper was dry it was exposed under the negative. This was done at a *south* window. The pressure frame had wheels, and ran in and out upon a horizontal railway, and the window had a shutter, which worked up and down like a guillotine. A leaden pipe passed from the developing room to that in which the prints were exposed, and the girls that were developing used to send messages along the pipe to the girl who was exposing, to tell her what exposure to give, whether more or less. The exposure varied from three to twenty seconds, according to the light. The paper was laid upon a plate glass, the negative upon that, and another plate glass put upon the negative. There was no flannel under the sensitive paper, which was wrong, and the definition suffered greatly in consequence. Blotting off the free nitrate was another cause of bad definition. The faintest imaginable trace of the picture was visible on its removal from the printing frame.

"The nitrate bath was 40 grains to the ounce, acidified with four drops of nitric acid.

"The sensitive papers cut to the right size were taken in a card-board box to the girl who exposed them, and when exposed were taken away in another similar box. She worked by the light of a *bougie* when the guillotine shutter was down; but a pane of glass, covered with yellow calico, would have done equally well. How easy it is to find fault with another man's arrangements.

"The developing dishes were about 30 inches long by 20 wide. The bottom was made of plate glass, and this was let into a wooden frame about 2 inches deep. The sides and corners were built up inside and made watertight by means of wax and resin. A great many prints were developed together in these dishes, and they were repeatedly turned over and moved about in the gallic acid. The dishes were only washed in the evening when work was over, and all the prints, those beautiful ones in the "Album Photographique de l'Artiste et l'Amateur," were at first covered with marbled stains, which were easily sponged off afterwards. The hands of the young ladies who developed the prints were as black as a negress's—and when not engaged in that work, these same young ladies used to earn their dinner by digging potatoes in the neighbouring fields, or milking the cows, and churning the butter—one day printing views of the Parthenon or Edfou for the "Photographic Album," and the next cleaning out a cowshed, or peeling mangold wurzel. It would be odd if a Regent Street photographer could not beat these French peasant girls at printing by development, if he chose, and after he has been told how they did it.

"The prints were developed in a very hot room, temperature up to 80° at least. The time occupied by each print was about twenty minutes, and several girls used to stand at the same table, each with her dish full of prints, in various stages of development.

"As soon as a print was fully out, it was carried into another dark room, drained for a few seconds, and then put into fresh hypo, strength 5 per cent. Here it remained twenty minutes, and was then put into a second lot of fresh hypo of the same strength, in which it remained another twenty minutes. The first of these hypo baths was called the toning, and the second the fixing bath. If the print had been washed, and the first bath too strong, it would have been too much reduced, and the colour would have been red and rusty. But the unwashed print communicated slight toning properties to the first bath, and produced the exquisite colours for which M. Blanquart-Evrard's prints are remarkable. The fact of their permanency, notwithstanding this slight sulphur toning, arose from the large excess of silver over sulphur in the print. There was not enough sulphur in the paper to convert the whole of the silver into the yellow sulphide. In a developed print the mass of material which form the shadows is much greater than in a sun-print, as may be easily seen by holding both up to the light. Hence the superior permanency of the former under the action of small quantities of sulphur.

"Sometimes gold toning was employed, but that was the exception and not the rule.

"After the toning and fixing came the washing. In the basement of the building there was a large room containing several monstrous tanks, each having a perforated false bottom which could be lifted up and down. Into these the prints were put, and frequently moved up and down, and the water changed every half hour. A few hours treatment of this kind was considered sufficient.

"After a print was thus thoroughly washed free from hypo it was put into a bath of water acidified with hydrochloric acid, and this removed a yellowish deposit from the pores of the paper. The print was then washed again, and hung up to dry. When dry it was hung over a line in a glass room at the top of the house and there exposed to the full action of sun and air for several weeks, and this greatly deepened and improved the colour, by converting its redness into purple-black.

"The print being now finished, it was trimmed, and mounted with starch, and then placed in a press between hot plates of iron.

"Troublesome as all these operations may appear you are repaid for all by a print of extraordinary beauty of colour, both in the lights and shadows. If we are compelled to admit that in many of the prints published by M. Blanquart-Evrard there is a little want of definition, and of justice done to the negative, yet this fault does not seem to be attributable to the process, but rather to the mistakes in the manipulation to which we have already alluded—viz., blotting off the free nitrate, and not putting any flannel into the printing-frame. It is a pity that these faults were permitted, because as photography advanced, and negatives became sharper and better, the eye of the public seemed to crave after mechanical excellence rather than artistic effect, and albumen prints carried the day. But a vitiated taste will not last for ever, and the good time will arrive sooner or later when photographs of artistic subjects will have to be printed in an appropriate style, and then it may be proved that artistic treatment and mechanical excellence are not incompatible qualities, as they seem to some people to be now.

"Any good kind of photographic paper, French, English, or German, may be used for gallic acid printing, but they do not all yield the same colours and effects. By varying the reader will quickly discover which is the best for his purpose. He cannot go far wrong with any of the good samples of photographic paper.

"The colour of the print may be modified by a longer or shorter time over the hydrochloric acid. You will observe in every print before it is trimmed that the marginal part of the iodized paper which rested upon the lid of the leaden bath of acid, and consequently received less of the fumes, is grey and devoid of vigour, and at the same time over-exposed, so that the effect of the fumes of the hydrochloric acid is to give redness and vigour to the print.

"Out of the thousands of prints developed upon iodized paper at the establishment at Lille, which have passed through our hands during the course of five or six years, and of which we have since been able to hear, only two or three have faded. One can easily imagine that out of a large number of prints a few may have escaped washing altogether. But if a high degree of permanency must be granted in the case of prints developed upon *iodized* paper, the same is not true to an equal extent in the case of prints developed upon *chloride* paper. We have known many of these fade."

CRYSTAL PALACE SCHOOL OF ART, SCIENCE, AND LITERATURE.

The establishment of Classes and Lectures, which should in a proper manner utilize, for educational purposes, the vast and unequalled resources of the Crystal Palace, is now, we understand, no longer a matter of conjecture, but a tested fact. The School was commenced last year, and during the whole of last season progressed; the result, at the close of the first term, being highly satisfactory. The classes developed were those for ladies, and all the plans were carefully laid accordingly; but it is understood that the operation of the movement is not to be restricted to this, but to receive every practicable development. The services of professors of the highest rank in each study were retained, and in every feature of the organization the greatest care was exercised by the Committee that the highest character should be maintained in the instruction, and in the Lectures; and that the privacy and comfort of the Studios and Rooms provided, should be equal to the immense advantages in other respects; the instruction being, indeed, more a system of private lessons, with the luxury of the drawing-room, than in the commonly received mode of holding classes. The result has been in every sense satisfactory. The first families in the surrounding and increasing neighbourhood of the Palace have warmly taken up the advantages offered, and families from all parts of the country have taken residences near, that their daughters might enjoy the advantages of the masters, as well as a pleasant visit. The regulations and announcement for the new term, which commences on the 1st of November next, and continues till July 31st, 1862, have just been issued. The classes for Water Colour Painting, &c., are taught by Mr. E. A. Goodall; those for Figure Drawing and modelling, by Mr. W. K. Shenton, and for these the magnificent Art Collections of the Palace are all available. English is taught by the Rev. Philip Smith, B.A., and Professor Mariette of King's College, London, takes the French. Dr. Kinkel instructs in German, and no doubt will also give some of his famous lectures on the History of Art, delivered with such success at the South Kensington Museum. Italian is by Signor Volpe; and Latin as well as History, by the Rev. C. Boutell; Herr A. Sonnenschein, is the Professor of Physical Geography; Dr. Dresser, of Botany; Dr. E. Lankester, of Physiology, and Dr. D. S. Price, the Director of the Technological Museum, of Chemistry and its applications. For the Pianoforte, there are Messrs. Benedict, Lindsay Sloper, and Prout; Singing, the great Garcia, Mrs. Street and Miss Whyte; for Part-singing, Mr. Henry Leslie and Mr. J. G. Calcott, while M. Louis d' Egville teaches the Dancing. The first courses of Lectures will be by Dr. Dresser and Dr. Lankester, and will commence on the 17th inst. Dr. Dresser's will be on the "Arts of Decorative Design, and their relation to Botany," and will be specially addressed to those who may be preparing to exhibit in competition in the International Exhibition of 1862. Dr. Lankester's will be on the "Physiology of the Nervous System, in relation to Health and Education."

We have only one regret in connection with this subject; that is, that no class for instruction in photography exists. We cannot but think from the unusual facilities of the place, a valuable class for affording amateurs instruction and practice in photography, might be established. We presume that existing arrangements with the firm who contract for the photographic department of the Palace, may at present preclude the establishment of such a class. It is not, however, the less a matter of regret, and we commend the subject to the attention of the directors in any future arrangements which may be made.

A CHAPTER OF HINTS.

Sir,—Perhaps the following method of mounting photographs cheaply and neatly, may interest some of your readers. Having mounted the picture on card, as usual, lay it, face downwards, on a clean sheet of glass of the same size as the cardboard; bind the edges together with a sort of stiff, leather-like, coloured paper (which can be got at any stationers), making, in fact, a sort of passepartout; rings can be put on tape, gummed on the back of the picture, and the whole back covered with marble paper; this can be applied to large pictures at a very trifling expense. If liked, a narrow edge of gold stamped paper can be put round the face of the glass, over the edge of the binding paper.

Among a few dodges I have found very useful, let me say a word for a very handy plate warmer, described by Mr. Gutch, some months ago; it answers well for drying dry plates; a very small quantity of hot water warms it, as the steam fills it; mine cost 3s. 6d.

Plates can be easily heated, for varnishing, over the chimney of a moderator lamp, being careful to keep the plate moving, to heat equally.

A very handy thing in the dark room is a common biscuit tin, about a foot square, and open at the top; it serves for putting plates in to dry, with a cloth over to keep out dust, and is better than a grooved box, as it does not tear the edges. I also put my Gutch's warmer in it to dry dry plates out of the way of dust.

The best washing bottle I have yet had, is a preserve bottle, with a large mouth, in which is a cork, with a piece of tin tubing, the mouth of which can be pinched to any shape; where economy of water is an object, not a drop is wasted with this.

Lastly, let me advise everybody to keep a photographic memorandum-book: I merely enter enter in mine a word or two to direct me to the journal where I have seen the information on any subject I may require hereafter; so on turn-to my book, and the heading on which I want to know something, I find references to the subject to many places. I have found little bits of dodges, like the above few, so useful to myself, that I venture to think others may derive some benefit from them.—Yours obediently, G. Smith.

PROPOSED IMPROVEMENTS IN PHOTOGRAPHIC LENSES.

BY PROFESSOR EDWIN EMERSON.*

Sir David Brewster, in his "Treatise on the Stereoscope," repeatedly and earnestly insists on the importance of taking the photographic negatives by a lens of very small aperture; he gives as a general rule, "an aperture as large as the pupil of the eye;" and he makes also the following declara-

* From Humphrey's Journal.

tion:—"I have no doubt that when chemistry has furnished us with a material more sensitive to light, (than that possessed in 1856), *a camera without lenses and with only a pin-hole will be the favourite instrument of the photographer;*" in the meantime, however, he suggests that "the use of a lens of rock-crystal, which has a low dispersive power, and having the ratio of the curvature of its surfaces as six to one, with an aperture of one quarter of an inch, would make an approximatively perfect camera."

Being convinced, by the excellent results obtained by myself, that a small aperture was indispensable to success in point of sharpness, which was a confirmation of Sir David Brewster's main idea, and having been furnished, by my friend Professor Rood, with an instantaneous collodion, I began to test, by careful experiments, Brewster's notion of a pin-hole camera, and also the use of a quartz lens for the camera; I also endeavoured to determine approximatively how small the diaphragm of the ordinary photographic camera should be reduced so as to secure the best results. The instrument in my possession is a very excellent stereoscopic camera, fitted with two portrait combination tubes, and the best achromatic lenses of Harrison's make. The results were either obtained by this camera or were compared with its work.

Photographers generally focus upon the ground glass of the camera with the unaided eye, and of course, in a majority of instances, get only an accidental approach to a perfect focus; and when the aperture is over half an inch, for lenses of 6 or 8 inches focus, only a small portion of the whole picture is in focus at all. Those who use a magnifying glass, and a small diaphragm succeed better, but by neglecting to reduce the diaphragm to a minimum, their results are by no means as perfect as they might be. By the aid of a common magnifying glass one and a-half inches in focal length, with which to view the image on the ground glass of the camera, and an aperture of two-fifths of an inch in the diaphragm in taking the negative, I was able without any difficulty to obtain results fully equal in point of sharpness to the best French transparent views. But in attempting to improve upon this, by reducing the aperture, and by increasing the power of the focussing lens, two difficulties were experienced—1st. The light was so much diminished that it was nearly impossible to see minute shades of difference in the sharpness of definition, and, 2nd. The inequalities of the finest ground glass were so much enlarged, as seriously to obscure and distort the view projected upon it. This last proved an insuperable bar to any higher degree of excellence by these means, as a singular irregularity in the ground glass was magnified quite enough to obscure many fine details.

Moreover, with a small diaphragm of the size recommended by Brewster, the light was so faint that a variation of half-an-inch in the distance of the lenses of the camera from the ground glass produced no *perceptible* variation in the sharpness of the image. A series of experiments was then made with two objects in view,—1st. To carry up the power of the focussing lens, and, 2nd. To substitute for the ordinary ground glass of the camera something of finer texture, so as to stand the microscopic enlargement, and of more transparent quality, so as to increase the light. An ordinary Fothergill plate, covered with the delicate yellowish film of iodide of silver enabled me to carry the magnifying power to fifteen diameters, with an aperture of one-fifth of an inch.

At the suggestion of Mr. Grunow, of New York, a plain glass plate, lightly covered with dust, was tried, which, with a power of fifteen diameters, rendered practical the employing of an aperture of three-fifths of an inch.

But in all the experiments with a single microscope the focus was too indefinite and uncertain for the accurate work I had in view, although the sharpness obtained was far beyond anything I had seen produced by the professional photographers. Indeed, among both British and American artists and amateurs in photography there seems to be a wide difference of opinion as to what may be regarded as *a standard* on this important point. I have not seen a suggestion of the proper means of determining it; which is, undoubtedly, an appeal to the compound microscope.

At this stage of the investigation Professor Rood constructed for me a compound microscope of a power of thirty diameters, which I hoped to be able to employ as a focusser.

This instrument I had intended to use upon the focussing plate of plain glass delicately covered with dust, but it occurred to me that plain glass alone would answer to focus upon, and if so, all the obstruction caused by magnified particles of dust, and the want of sufficient light, caused by the opacity of the Fothergill film, or anything of a similar character, might be entirely overcome. A trial showed that the amount of light was greatly increased; but I was now unable to determine the position of the image projected by the lenses of the camera. The lenses of the camera in connection with the lenses of the microscope formed a telescope of considerable power, the lenses reciprocally supplementing each other, so that no matter where the image produced by the lenses of the camera might be formed in space, the microscopic focusser could be readily adjusted to suit it, and give a perfect view.

To obviate this uncertainty, fine parallel lines were drawn by a diamond, one-twentieth of an inch apart, upon the surface of the plain focussing-glass nearest to the lenses of the camera; the microscope was then carefully adjusted to distinct vision of these lines, and its lenses fixed in that position. It was now easy to cause the image formed by the camera to coincide in position with these parallel lines, and thus the perfect physical focus for the sensitive plate was absolutely determined, allowance, of course, being made for any difference between the chemical and visual foci, which this arrangement afforded a means of adjusting with the greatest accuracy.

By this method of focussing very small objects, such as a single leaf of an elm over half a mile distant, were distinctly visible, and were readily focussed upon; and also the difference in the focus of objects at a mile, and those at a mile and a half in distance, was made apparent; which is utterly beyond the power of the single microscope.

The use of a small diaphragm enabled me now to secure the very finest details in all the objects visible in an extended landscape, so that they would bear examination under the compound microscope with a power of 150 to 200 diameters; or, in other words, with a power as high as the structure of the collodion would bear. Up to this I had supposed that the lenses of my camera were of the same focal length, as very delicate manipulations had failed to detect any discrepancy between them; but by this method of focussing, a variation of nearly one-fifth of an inch was detected immediately. By the use of the instrument the aperture was reduced to one-tenth of an inch, which from careful experiments I regard as about the minimum for good results, for lenses of six inches focus.

I was now prepared to test the ideas of Sir David Brewster, 1st. With regard to a small aperture. 2nd. With reference to a rock-crystal lens; and, 3rd. As to a pin-hole alone substituted for a lens, in connection with a very rapid collodion.

By means of the binocular camera I was able to make two experiments simultaneously, on the same plate, the left hand view being taken by the portrait combination, and the right hand view being taken with a quartz lens, or a common glass lens, or a pin-hole, as the case might be. The scenes, or objects photographed, were always exposed to the full light of the sun; and the plate, in each pair of experiments, was, of course, subject to a uniform treatment, under similar conditions as to collodion, baths, &c. I was thus able to compare the results of the various experiments, side by side, with the action of the achromatic combination.

The results of these experiments may be summed up as follows:

1. It is found in practice that a quartz lens is quicker in action than a common glass lens of the same aperture, focus, and thickness.

2. A quartz lens is very slightly quicker than the double combination of achromatic lenses; but it will not afford anything like so sharp details, even under the smallest diaphragms. "A quartz lens camera, with a quarter-inch aperture," is, therefore, very far from being "an approximatively perfect camera."

3. The simple pin-hole will not compare under any circumstances with the commonest glass lens, as it gives no sharpness to the picture, and requires from three to seven minutes' exposure, with the most sensitive collodion. This lack of sharpness might have been predicted theoretically. To give sharpness to the image, the pin-hole must be as small as the smallest detail in the view required, say the ten-thousandth of an inch, otherwise the rays of light from a single point travelling such paths as are indicated in the diagram produce necessarily a blurred image; thus sharpness will be in proportion to the smallness of the pin-hole; now as a pin-hole of the one-fiftieth of an inch in diameter requires with the most sensitive collodion an exposure of several minutes, it is apparent that a hole, the ten-thousandth of an inch in diameter, would require an exposure entirely impracticable.

We are compelled, therefore, to regard Sir David Brewster's pin-hole camera as an optical, as well as a photographical, absurdity.

4. The diaphragm for lenses, 6 inches in focus, can be reduced down to about an aperture of one-tenth of an inch with a very decided improvement in sharpness, if the compound microscope is used to focus with on a plain glass focussing plate: but when we reduce the aperture below this there is a loss of sharpness, owing, it may be, to the approximate parallelism of the rays.

5. A good use for a pin-hole camera would be as a simple instrument for testing the sensitiveness of collodions, and I would recommend it for this purpose.

PHOTOGRAPHY AND THE FINE ARTS.

BY COLEMAN SELLERS.*

That the war has begun in England between the photographic societies and Her Majesty's Commissioners is not strange. The exclusion of photography from the ranks of the fine arts seems to me very unjust. That art or employment which confers the greatest amount of good on the greatest amount of people, and at the same time calls for the exercise of the highest mental attainments on the part of the artist or operator is the one entitled to the greatest respect in its class.

The engraving or etching claimed among the "modern fine arts," is not the work of an artist, it is the work of a printer, who may be a very uneducated man with no artistic taste. The copper plate which produced the print is the work of the artist, and in the print we see the proof of the perfection of the artist's work. This artist, however, has but the one mental faculty called into play. He has acquired great skill in cutting certain lines, all according to certain fixed rules, and much—very much of his work has perhaps been performed by ruling machines and lathes, of the construction of which he is ignorant. If now an ingenious mechanic should arrange machinery that an oil-painting could by the machine be copied on a plate of copper, each shade and form reproduced by certain combination of lines and stipple, the print from this mechanical engraving would take its place among the works of great masters and enjoy the select society of the fine arts.

We know that a medal or other bas-relief can be engraved by a ruling machine in a much more perfect manner than can be done by hand, yet the product is a picture produced by a machine; that machine is then the artist, or the workman who turned the crank is, for the product of the machine is an engraving and can be admitted into Section 4 of the Great Exhibition. If now we take a step above engravings and into the domain of painting, let me not be charged with disrespect if I assert that it is more of a mechanical operation than photography. A grandson of Charles Wilson Peale, I claim as the descendant of a painter, a right to speak of painters, many of whom I am moved to say, have been my dearest friends.

* From the *American Journal of Photography.*

In old times before the making of colours became a trade, the pupil of a great master was first put to grinding paints; he was, through a long course of apprenticeship, taught to mix and compound from earths, metals, and vegetables, all the brilliant colours that were the special charm of his master's work. That the works of the great masters have in some cases been more permanent than that of others, was due to their greater skill in preparing their pigments. Here there was required a practical knowledge of the chemistry of the substances used, and scientific skill outside of painting. Now, however, the artist furnishing stores have put up in such neat little metal tubes, all kinds of tint and shades of colour that the modern artist is almost ignorant of the slab and muller.

It is better that this should be so, for the more all arts and sciences are subdivided into specific departments, to each of which the undivided talent of the operator can be given, the more advancement will be made in the arts generally.

But still, the taking of the mechanical mixture and grinding of paints out of the artist's hands does not make the remaining opeeration any the less mechanical. His genius may point out to him a grand subject, but to work out that subject he looks about him for matter to copy—ideal faces are in most cases portraits of living people.

The artistic skill is thus divided into three departments:—The genius of conception, judgment in the selection of subjects to act as models in the composition, and skill in imitating the appearance of the model. The two first are as necessary in photography as in any of the other graphic arts, and of the last I would like to say a few words. Painters have their own touches peculiar to their manner of handling the brush and using their colours. These peculiarities are copied as far as may be one from another; they have their tricks of trade, and he is the most skilful who has at his finger ends the most ready resorts to produce effect. Any one who has heard artists comparing notes will know how true this is. There has been a veil thrown around the painter's studio,—and the stamp of genius placed on the works of the favoured ones.

They have been lifted above the mere mechanic, and they have remained seated even while royalty has done them homage. As far as I am concerned Her Majesty's Commissioners have done no harm in excluding photography from the fine arts and placing it in the more useful 2nd Section of the Great Exhibition.

The question, however, is, as to whether they have made a proper classification when they so place photography? I must confess that it was with surprise I found no mention of the art in the enumeration of the classes of the 4th Section, and thought for a moment that photography had been ignored, nor was my surprise diminished when I found it in the 2nd Section. The cultivated mind of man seeks to reduce all things to order by proper classification and what reason there can be for the exclusion of photographic pictures from the society of pictures made by other processes is more than I can understand.

A print made by any of the new carbon processes is as much a photograph as those made with the salts of silver. The composition of the colouring matter of these carbon prints is the same as the black in the printer's ink of an engraving; these are both pictures, may be of the same subject, and yet forsooth, the photograph cannot be classed with its more fortunate rival, and is excluded from the select company of the fine arts. The truth of the matter is, photographers are looked upon as men who, without any scientific skill, slop a plate with collodion, dash over it sundry liquids, and lo! and behold! a picture is made, in far too easy a way to be genteel. If it did but require some weeks of labour to make one good negative, then it would be a work of art, instead of being considered the sloppy amusement of men who have not the talent to draw.

Permit me, in refutation of this erroneous notion, to sketch a photographer as I know many to be, and then I will let my readers be the judges whether or no he is an artist, and whether his work should not be classed with the fine arts.

In the first place he must be a willing student of books, well versed in chemistry, a student of nature, with a keen perception of the beautiful. If he be inclined to portraiture he must be a gentleman easy of manner, and of such address that he can give ease and assurance to the sitter. He must at a glance see their character and notice their peculiarities. He cannot hide their defects as a painter can, but he must study to throw them in the shade. And if he desires to make his picture a beautiful composition he must, in the shortest possible time, group around his sitter such accessories as will suit the character; to complete the picture a background is need; he has sketched a clean sheet of white flannel, on which, with a practised hand, he draws with charcoal, in rapid strokes, a landscape suited to the sitter; his knowledge of effects shows him how to work up his various distances, and produce the best result. All this must be the work of a few minutes.

Then comes the delicate study of light and shade; on the face of age the deep furrows of time, tinged red by the light falling through the overhanging flesh, look not like shadows in nature, but he knows that in photography they are the darkest shadows imaginable; hence, by ingenious reflecting screens he must, without destroying the shadows needed for rotundity, light up these wrinkles by other rays; he must study the amount of light on the eyes, taking care not to make the white spot or high light too large.

Then while anxious about the delicate manipulation of the dark room, he must, by his easy manner, give assurance to his sitter, that the face may be lighted into animation, and not frozen into rigidity. His chemical process must be conducted with such certainty of success that failures must never depend on himself, but always on the sitter.

The picture thus produced is more truthful than the most pre-Raphaelite production of painters' skill; it has required in its production talent of the highest order, and yet even if printed with carbon, as an engraving would be, it cannot be classed among the *fine arts.* Let not what I have written be considered as detracting from the merit of artists, far from it; but as a passionate lover of good pictures, no matter by what process made, I must speak my mind freely, and say a good word for that art which of all the arts of design is most likely to confer lasting benefit on all mankind.

PHOTOGRAPHY IN A COUNTY COURT.

Beard *v.* Lady Holland.

In the County Court of Surrey, holden at Chertsey, September 21st. Before John Farquhar Fraser, Esq., and a Jury.

This was an action brought by the plaintiff, who is a travelling photographer temporarily located at Weybridge, against The Right Hon. Lady Holland for the sum of £22 10s. for 180 photographic views of St. Ann's Hill, her ladyship's seat at Chertsey.

Mr. Pearce, instructed by Mr. Binns, of Trinity Square, Southwark, appeared for the plaintiff, and Mr. McIntyre, instructed by Stephens and Matthews, of Essex-street, Strand, for Lady Holland.

It appeared that the plaintiff in the month of July last had solicited permission from J. H. Browne, Esq. (Lady Holland's architect and agent), to take some views of St. Ann's Hill for a work to be entitled "Seats in Surrey," which he alleged was about shortly to be published. This being consented to by Lady Holland, some specimen-views were taken by the plaintiff and sent into the house for Mr. Browne to look at. As he had been recently engaged in making extensive improvements to the house and grounds, of which he was desirous of having some views taken, he agreed with the plaintiff to take ten different views, and to have supplied to him ten copies of each, the plaintiff offering to do them at 2s. 6d. each, or £12 10s. for the series,—the agreement being that the views should be well and carefully taken, and that advantageous times should be selected so as to get a good effect as regards light, &c., and that perfect photographs should be supplied. Spots from which the views were to be taken were marked out, and a memorandum of the order entered by Mr. Browne in his pocket-book. Two or three of the views were taken, and submitted for Mr. Browne's approval; but he pointed out many defects, which the plaintiff promised to correct in the others. Nothing more was heard of the plaintiff till some time in August, when he brought to Mr. Browne, at his house in Bayswater, 200 copies of seventeen different views. Of the ten views ordered by him only nine had been executed—those not in accordance with the order—and all very badly and carelessly taken; some evidently had been taken in the rain, others on a windy day. They were at once rejected by Mr. Browne, as not being in accordance with his order and the plaintiff's agreement, and from the badness of execution were useless to him.

The plaintiff was examined in support of his case, and stated that he had been a photographer sixteen years, and that he had received the order from Mr. Browne for eighteen different views; that he had seen Lady Holland on the lawn, and in the drawing-room, and in one of the halls, and that on one occasion she had looked through the camera and admired the view, and that Mr. Browne, in giving him the order, had asked him for how much he would take her ladyship ten copies of each view, and that he considered he was taking the views for Lady Holland.

Mr. Parry and Mr. Powell (of Chandos-street), photographic artists, were called by the plaintiff, and said that the photographs were good fair pictures, and that they could not have supplied similar ones at the price charged; and that in their opinions the retail price for such views would be 7s. 6d.

At the conclusion of the plaintiff's case, Mr. McIntyre submitted to His Honour that no order had been proved to have been given by Lady Holland, and that an order for photographs was not within the general scope of agency, and that the plaintiff's case against Lady Holland had failed. His Honour, however, considered there was sufficient evidence to go to the Jury.

Mr. McIntyre then addressed the Jury on behalf of Lady Holland, and after going through the facts of the case commented severely on the action having been brought at all against Lady Holland; the only reason for so doing having been, he said, evidently to frighten her ladyship into paying an unjust demand.

On the part of Lady Holland, Dr. Diamond, Secretary and member of the Photographic Society, and Editor of the Journal of the Society, having examined the photographs, pronounced them to be some of the poorest attempts at photographic pictures he had ever seen, and that the work had been very carelessly and negligently performed; that he would not have accepted them as a gift, as he considered them worthless. The plaintiff himself having stated that his camera was blown over by the wind on three occasions, proved how little attention he had paid to the selection of a proper time for his work. The witness exhibited some pictures lately taken by Mr. Vernon Heath, illustrating the difference between a good and a bad photographic landscape.

Mr. Browne proved most distinctly that he had given the order for the ten different views for himself and not for Lady Holland; that when the plaintiff brought them to his house, he at once saw they were so badly done, and not in accordance with his order, that he refused to take them, and gave the plaintiff notice to take them away; instead of doing so, however, the plaintiff caused the present proceedings to be taken against Lady Holland.

His Honour, in summing up, after commenting upon the evidence, was clearly of opinion there was no evidence of any order by Lady Holland, but left it to the Jury to decide if they thought that any evidence had been adduced by the plaintiff of any authority on the part of Lady Holland to her agent to order the photographs, and to say if the plaintiff had sued the right party; and said, if the Jury were of opinion that an implied authority had been established, they must then consider the question of the quality of the photographs, and say whether the work had been properly performed, and in accordance with the contract.

The Jury returned a verdict for the defendant.—*The Photographic Journal.*

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 23rd October, 1861.

The new photographic process announced by Professor Balsamo, of Lecca, which appeared in No. 154 of The Photographic News has been submitted to a practical test by Dr. Schnanss, who pronounces emphatically against it. He says, "this process, which contains so many new facts both in chemistry and photography, greatly astonished me on perusal. But, as is justly remarked, we must prove before judging. Acting on this principle, and upon another, *nil admirari*, during my career as a chemist and photographer, I have learned to make such experiments with sufficient circumspection to enable me soon to recognise truth from charlatanism. I never allow myself to be convinced by a single experiment, but repeat it three or four times before forming a conclusive judgment upon the process in question; for I very well know that to succeed with the simplest process, we must follow a certain routine, and that failure is frequently attributed to processes when the fault really lies in the unskilfulness of the operator. I have proceeded in this manner with Professor Balsamo's process. Like all chemists, I was ignorant that phosphorus dissolves in hydrochloric acid without undergoing any change, or that light caused it to give a flocculent precipitate. This curious fact did not, however, appear to me impossible, so I commenced my experiments by digesting some pure phosphorus in concentrated hydrochloric acid, and putting the bottle containing it into a vessel of hot water for several hours. The phosphorus became liquefied, exhaled much vapour, but did not dissolve at all. I remarked that the phosphorus liquefied by the hydrochloric acid retained this form after cooling several days; but the moment it was touched by some hard substance, as a glass rod for instance, *it hardened immediately*, as much so as before its liquefaction. This phenomenon does not appear to have been observed previously.

I left the phosphorus for four weeks longer in the hydrochloric acid, but I did not discover the least tendency in it to dissolve. To one portion of this acid, I added the concentrated solution of acetate of copper, until the liquid assumed an orange tint. Some chloride of copper was doubtless then formed. In this solution, I immersed (in the dark) some sheets of paper, which I left in it for a space of time varying from five minutes to five hours.

After completely drying them in the air, the paper was still further dried over a lamp, because Professor Balsamo stated that paper was sensitive only when perfectly dry. In this condition the paper assumed a yellow colour, which, however, disappeared on exposure for some time to the air.

The dried paper was then placed beneath a negative, covered with a sheet of bibulous paper, and exposed in the pressure-frame to the direct light of the sun, for various spaces of time, the longest exposure being four hours.

Not the slightest trace of a picture manifested itself: the paper did not even acquire a grey tint, it only became white, as stated above. This phenomenon proceeds from the humidity of the atmosphere, and has not the slightest connection with the pretended photogenic properties of the cupro-phosphor hydrochloric solution.

However, I did not despair, but repeated the printing process five times, still with the same result—failure! Finally, I placed my hopes in the developing power of sulphuretted hydrogen. Having filled a porcelain capsule with sulphate of iron, I poured on it some diluted sulphuric acid, and covered the capsule with the paper I had exposed to light in the pressure-frame. This also was attended with a fruitless result. The paper acquired a general brown colour, which became deeper when the paper was moistened, but without showing the slightest trace of a picture.

As all my efforts were abortive, I have thought it my duty to publish the results to prevent photographers from wasting their time unprofitably, in experimenting with phosphorus, as well as to show how eager charlatanism ever is to glide into the domain of true science. It is sufficient to compare the simple and excellent tannin process of Major Russell with this pretended new phosphorus printing process, with its pretentious theoretical explanations, possessing no value whatever, to be convinced of the truth of the assertion above made.

PHOTOGRAPHIC EXCHANGE CLUB.

Dear Sir,—I was glad to learn from last week's News, that the "Stereoscopic Exchange Club" is about to be re-organised; and there seems little doubt but that the scheme now proposed will give universal satisfaction, provided the judgment of the gentlemen acting as referees be given fairly and impartially; not that *I* entertain a doubt but that it will.

But my object in writing, is to offer a few suggestions relative to the new "Photographic Exchange Club."

The first being, that *portraits* of the *members* be admitted into the general exchange, each member sending two, three, or more copies of his own portrait, to receive a like number in return—the name of the member to be written on the back of his portrait.

2. That some plan be adopted to prevent members having sent to them duplicate copies from the same negative, either portrait or view.

Permit me to suggest the following scheme: — Each member to number his negatives consecutively, from which he intends sending prints, each print having written on the back the number corresponding with its negative.

The secretary to be provided with a list of all the members, each name to be followed by the *consecutive number of his negatives*, thus:—"Tom Jones," 1, 2, 3, 4, 5, 6, &c.

Now, each member sending prints for another exchange, will accompany them with the names of the members, and the consecutive numbers of the members' prints he is already in possession of; so that the secretary, on referring to the list, will at once see which prints he has before sent. For example, suppose I have got prints from Tom Brown, Frank Fairleigh, and Harry Coverdale, and I wish to send off another batch for exchange. Now, it is just possible that I might get copies of the same prints over again. My plan would obviate this, in the following manner:—I send off prints for exchange; on a slip of paper, which accompanies them, is written,—

"Tom Brown," 3, 5.
"Frank Fairleigh," 4, 6.
"Harry Coverdale," 1, 3, 5.

Now, the secretary, refering to his list, will see that he has not to return prints 3 and 5 of Tom Brown's number, nor prints 4 and 6 of Frank Fairleigh's number, nor yet prints 1, 3, 5, from Harry Coverdale; but any of the other numbers which follow their names may be sent in return.

Apologising for troubling you with the above suggestions, I remain, yours, &c., R. M.

Bamber Bridge, Oct. 22nd, 1861.

Talk in the Studio.

Architectural Photographic Association.—We regret to announce that this association has ceased to exist; that it has, in fact, from several causes, proved a failure. The stock of photographs, &c., we see are announced for sale.

New Electric Light.—The *Times* Paris correspondent says:—A trappist, named Delalot-Sevin, of the Abbeye de la Grâce-Dieu has made a discovery which will probably produce a revolution in the system of lighting and heating public and private buildings. He has invented a new pile, much stronger, and at the same time much cheaper, than the pile of Bunsen. By means of his photo-electric apparatus he produces an electric light as cheap as gas; and with his thermo-electric pile he supplies caloric on economic terms hitherto unknown Several of these apparatus have been constructed, and one is at full work in the Abbeye de la Grâce-Dieu. Manufactories for the public are shortly to be established in Paris, and at Lyons. The apparatus for producing gas will not be given to the public until after the Exhibition at London, next year; but that for heating buildings will be made public on the 16th of December next. The inventor has been authorized to make public experiments with his system of lighting on the Place Saint Jacques in Paris, and on the Place Bellecourt, at Lyons.

Photography at the Exhibition of 1862.—Mr. Leighton writing to the *Journal of the Society of Arts*, says: "Perhaps in no art has there been greater progress made, since our last decennial Exhibition, than in that of photography—an art that, by the use of collodion, has risen from a mere toy to a giant power and boundless pleasure—a power that I hope may not be turned against us in 1862. Photographers must be up and stirring if they want to compete with the results I have seen in the northern capitals of Europe, and which, doubtless, are to be found in the south also. I allude to the life-size portraits taken by the action of light, of heroic proportions and artistic worth, reminding one of the best works of such great masters as Rembrandt, Reynolds, Velasquez, and Opie. I know it is the idea here that objects the size of life cannot be done satisfactorily to compete with the works of our artists—a great mistake, that we may find to our cost in next May. If we had nothing to contend with save the miserable heads exposed in one or two of our leading thoroughfares—great faces, or rather "likenesses," without expression, being libels on humanity in general and individuals in particular—we should have little to fear; but such is not the case. From Berlin, Dresden, the Hague, Aix la Chapelle, and Brussels, we shall have first-rate full-length portraits, looking more like grand paintings in sepia, than tarnished silver fixed by a chemical process, independent of the artist's touch as I presume them to be, though some hold otherwise. All I can say, from several at present exhibiting at an Exposition in the Palais du Prince Héréditaire, at Brussels, is, that if touched by artists they are a great credit to their powers, and the result highly satisfactory; but I do not believe nature in this case has required such aid or had it. At Brussels, in the Exposition I name, are several life-sized portraits, remarkable for breadth of effect, and artistic treatment; a half length of a man, in a loose coat, with a broad felt hat in his hand; and another of a gentleman reading, on a bed, or couch, much foreshortened; also one of the Emperor of the French, I think taken from a small album portrait. The miniature painters' occupation is nearly gone, and we may, perhaps, see the second-rate portrait painter also superseded, and the same negative made to print pictures for the walls of town-hall, or mansion, or for the album in the lady's boudoir.

To Correspondents.

M. D.—The cause of the snowy appearance in some stereo prints is a slight amount of hardness caused by over development, or too free use of silver in development. The delicate little secondary lights which surround the high lights, are all buried, and constitute, with the high lights, so many snowy patches of light. This becomes much more obvious when the prints are examined in the stereoscope, although quite apparent to the educated eye without the stereoscope. The softest and most delicately detailed pictures are best for the stereoscope, as they will appear perfect with its aid, even when to the eye alone they look feeble and lacking in brilliancy. 2. The silver bath for sensitizing paper should be slightly acid; because it gives more brilliant prints, does not so rapidly become discoloured itself, nor does the paper so rapidly discolour in the dark as when it is neutral or alkaline. A little nitric acid is best, but very little will do. 3. Mr. Fry published a method of making the silver bath so that it should not discolour, which consisted in the use of common instead of distilled water, and never filtering out the precipitate; but always leaving it in the bottle, and shaking up with the solution. A bath made in the ordinary way will not so soon discolour with acid, as we have just said. Floating the paper previously on alcohol is of no use. We shall shortly have something to say on this subject more fully.

T. K.—The American photographic journals can be obtained through any of the American booksellers' agents in this country, or direct from the offices of the said journals.

W Smith.—The composition of the preparation called "Alabastrine Solution" is a trade secret. Various recipes have appeared in our columns for solutions intended to produce similar results. In all cases the bases is bichloride of mercury; various additions have been tried with a view to modify the cold blue tone which is generally produced by that agent alone; but we are not aware that any of them have suceeded so well as the solution named "alabastrine."

J. H. J.—As a rule, the quantity of citric acid should be about half that of the pyrogallic acid.

R. Gornon.—The markings in the sky are the result of the developer having been repelled by the film in those parts, and as it has acted energetically, development has commenced before the plate was perfectly covered again. The collodion of which you speak is sometimes apt to repel the developer, causing it to flow as if the plate were greasy, especially if in hot weather one end of the plate has become partially dry There are two or three modes of avoiding this:—first the addition of a little more alcohol to the developer, which will make it flow over more readily; next using a much weaker developer, so that its action is not so rapid, giving time to get the plate well covered before development commences; next, to wash the plate entirely with a little distilled water before developing, and then add this water with the free silver it contains, to the developer, and finally to use a large quantity of the developer so as to cover the plate with a rapid sweep. In hot weather, and with large plates, it requires very skilful manipulation and use of every aid to avoid such marks. The picture is much finer, however, with those slight marks, on the tinted sky, than it would be with a white one. The subject is a very good one, and would not be spoiled if an inch of the stained part were cut off.

W. R. A.—The blisters to which you refer are doubtless due to the paper. All samples of *Rive* paper are more or less subject to these blisters, but as that paper gives more brilliant prints than any other, and as the blisters generally disappear on drying, it is not always a matter of sufficient consequence to lead to the rejection of the paper. The cause of these blisters is uncertain. 2. The proportion of acetate of soda to be used in the toning solution is not arbitrary; different operators vary it to suit their own taste. We have found about half a drachm to a grain of gold the best proportion. Experience is the best guide in these matters. When you wish to try any formula, always take it, in the first place, as you find it. If it answer, well; if not, then there may be propriety in considering whether it is to be given up altogether, or only modified.

G. G.—We have not generally been pleased with the action of citric acid in conjunction with iron.

Iodizer.—You may mix the iodides and bromides of potassium, ammonium, and cadmium in collodion, in certain definite proportions, without disadvantage; but if you use the iodide of potassium with the bromide of cadmium, you had better not use more than about half a grain to the ounce of the latter, as there is a tendency to form the bromide of potassium by double decomposition, and that salt is not easily soluble in greater proportion than we have stated, and if formed it would be precipitated. There is an advantage in using the iodide of cadmium with either of the others you name alone, but we do not know of anything to be gained by mixing all three.

J. A.—We prefer the use of oxide of silver for neutralizing the bath. Add a few drops in water and agitate well: then filter 2. When the red spots which occur in toning, from the prints being in contact, or other causes of irregular or unequal action, are very marked, there is no remedy. When they are discovered before the inequality is great, they may, by continued toning, be obliterated without overtoning the remainder of the print.

J. L. Davies.—Strong silver baths, and highly iodized and bromized collodion, give the richest glass positives. Some persons like a strength of 48 grains of silver to the ounce. Where the bath is strong it should be very acid, otherwise it is difficult to work clean. 40 grains of silver, and 2 drops of nitric acid to the ounce, will give excellent results. 2. We cannot pronounce as to which is the best positive developer, as opinions differ. We have produced excellent results with many developers. 20 grains protosulphite of iron, 20 minims of glacial acetic acid, and 1 minim of nitric acid, form an excellent positive developer. 3. It is very easy to obtain instantaneous positives if the chemicals are in good order, the lens good, and the light sufficient. 4. We know of no simple way of uncovering the lens more rapidly than by means of a piece of cloth held in the hand and worked quickly. Dallmeyer's shutter is very good; and he is just bringing out another which is still better.

James Busby.—We see no reason why rain-water, filtered through a carbon filter, should not answer for every photographic purpose. We never use distilled water except in the silver bath, and the first washing of dry plates.

G. C. P.—We cannot tell you of whom you can get instruction in the preparation of photographic slides for the magic lantern. Various articles on the subject have appeared in our columns from time to time.

H. A., A Distressed Printer.—Your case, as stated, appears somewhat inexplicable. We have no doubt whatever, however, that the discolouration results from the action of sulphur. The fact that the prints of a purple brown tint when taken from the toning bath, turned a blueblack in the hypo, is alone very suspicious. But the prints themselves show numistakable proofs of sulphur action. We suspect that the fixing solution of hypo having been as you state, used before, was exhausted, and just had sufficient strength, on long immersion, to change all the silver in the prints into the insoluble hyposulphite of silver, which rapidly decomposed in the process of washing, producing the yellow brown tints that the prints possess. The only difficulty in this view of the case, arises from the fact that imperfect fixation generally presents a mottled-brown appearance known as the measles. The only way to account for the even brown tint is the half hour's immersion in the hypo, giving time to produce an effect throughout that is generally only partial. New hypo will remove the difficulty.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 165.—*November* 1, 1861.

PHOTOGRAPHY AND THE INTERNATIONAL EXHIBITION.

We have pleasure in announcing to our readers some satisfactory intelligence regarding this matter. We are authorized to announce that Her Majesty's Commissioners have decided to appoint a Committee to superintend the Photographic Department. This Committee will consist chiefly of amateur photographers, men of standing aud position, in whom, it is believed, photographers generally will have confidence. The list of names is not yet completed: we shall give full details in an early number. We are glad to be able to add that the number and reputation of the applicants for space, promise a satisfactory representation of photography.

ENGINEERING AND PHOTOGRAPHY.

Photographers have little dreamed, whilst enforcing their claims to a proper classification in the International Exhibition of 1862, of the heavy disgrace, and serious dilemma into which they were plunging themselves. The sad fact must, however, be announced. They have actually incurred the displeasure of the editor of a newspaper called the *Engineer.* He is, however, magnanimous, and does not intend entirely to crush the art, nor even to ignore it altogether. Here is the paragraph in which, blending severity with forbearance, whilst denouncing photographers, he still promises occasional recognition to photography:—

"Photographers have lately pretended to be so much affronted by having their works classed with those of engineers, by the Great Exhibition (1862) Commissioners, and have so strongly insisted upon separating themselves from us, that we are not disposed to show them any great amount of favour. For our part we never much coveted their company, believing that engineering art both requires, and secures, more brains than one is accustomed to find among photographers, and, consequently, that we should be degraded rather than otherwise by their society. But as we do not wish to be harsh, even to an inferior class of people, and as it is often useful for an engineer either to employ one of these photographers to take a picture of a machine for him, or else to take one for himself—which he can often enough do very well—we shall continue to give photography an occasional place in our columns."

The writer of the above paragraph seems to be incapable of perceiving that two things may be each equally respectable, and yet have little or nothing in common. Photographers, in protesting against an anomalous and incongruous classification, have never for a moment been guilty of the folly and rudeness of depreciating mechanicians or their art. They have protested that photography was not a mechanical art, that its merits could not be tried by the same standard, or on the same principles as the mechanical arts. Surely, it would be the madness of folly to place in juxtaposition, and attempt a comparison of, the respective merits of a steam engine and a photograph. There is no point of analogy, no ground of comparison between them. The most cunningly devised power-loom, or the most efficient steering apparatus, might receive small justice if they were to be examined for their pictorial beauties. Photographers desire simply to be judged by the standard of excellence to which they aspire in producing their works. They aim at pictorial beauty, not at the display of mechanical ingenuity or engineering skill. There is nothing in their art to give scope for, or illustration of, mechanical excellence in any pre-eminent degree. It is no derogation to a hatchet to say that it will not do the work of a razor; it is no affront to a locomotive to say it is not a picture. It is one of the simplest canons of criticism, one of the most obvious dictates of common sense, that everything should be judged after its kind, tested by the standard of merit belonging to its own order, and by that standard only.

It is not because they arrogated for photography any position superior to that art which has claimed some of the proudest names in the history of civilization, such names as Watt, and Stephenson, and Brunel, that photographers have protested against the classification in which they found their art; but because the position was au anomalous one. Because it implied that their productions were to be estimated by their mechanical qualities, which, if they had any excellence at all, must be the very lowest merit they possessed. Because it implied, that the truth, the delicacy, the artistic qualities of their productions, were due only to a mechanical operation, similar to grinding a barrel organ. If photographers were to be judged by their mechanical skill, the best of them must necessarily take rank below the inventor of a patent smoke-jack or knife-cleaner. These do involve some, it may be a good deal, of mechanical ingenuity and personal skill. They must show the mind of the man. If photographs were simply mechanical productions, they might more forcibly illustrate the perfection of the machine which produced them, than the ability of the man who turned the crank and ground out the pictures.

Photographers protested against the first classification, not because they despise engineering skill, or mechanical excellence in those arts which display its triumphs; but because excellence in their art is not, and cannot be, illustrated by mechanical skill, and because they do aim at what, in pictorial art, is a higher standard of excellence. They asked to be associated with kindred arts, and not with those with which they could claim neither comparison nor affinity. Admitting to some extent the justice of their claims, Her Majesty's Commissioners have granted them a separate department, in which they will stand on their own merits, and with this we believe most photographers are content.

We will not imitate the petty rudeness of the *Engineer*, by affecting to despise engineers, or regarding them as an "inferior class of people" as he does "these photographers." We rather prefer to believe that such a writer is in no sense their representative, and counsel him in future to endeavour to discriminate more justly. In continuing "to give photography an occasional place iu his columns," let him be assured that the advantage will be rather that of his readers, than of the art he affects to depreciate and patronise.

DRY COLLODION, WITH ROSIN.

BY SAUNDERS VAN LOO, AMSTERDAM.

Every photographer who has experimented upou dry collodion, must have arrived at the full conviction that this question is not easily resolved. A multitude of recipes have been recommended, which doubtless give some sort of result, but none the desired one.

Among the best methods recommended, are doubtless those of Duboseq and Robiquet: the preserving processes in which resource is had to hygroscopic agents are almost entirely out of favour.

A modification, or rather simplication, of the amber process is found in the use of common rosin, as recommended by the Abbé Despratz. This is an excellent method, and the one I proposed to follow, when some months ago I undertook some researches upon dry collodion.

While operating, I soon discovered that the method in question gave rapid and satisfactory results, always on condition that the whole of the ingredients of the collodion were favourable to the formation of a perfect picture, without the fear of seeing the plate entirely fogged.

Sometimes, by chance, the collodion may be quite suitable to the end in view, and then the addition of some rosin is sufficient. I asked myself if it were not possible to establish the conditions of success in every case; that is to say, to prepare a certain dry collodion, with the object of rendering the method proposed by the Abbé Despratz more general; and after an infinity of experiments, I fortunately succeeded.

I shall give a description of the modifications which appear to me to be useful to effect in the wet collodion process, when it is intended to operate by the dry method; modifications which consist only in the *changed proportions* of the ingredients which enter into the composition of photographic collodion.

Although we encounter difficulties enough in the practice of photography by the wet collodion process, the dry collodion process demands still greater scrupulous care. To illustrate this fact, I will give an example: every operator understands that there are two ways of obtaining upon collodion a film of iodide of silver of a thickness and opacity suitable to photographic manipulations by the humid way. No difficulties occur if the proportions of the iodides or of the gun-cotton, vary a little. It is understood that in the wet method, a slight surplus of pyroxyline is equivalent to a little less proportion of iodide; and in like manner, a larger quantity of iodide implies a lesser quantity of gun-cotton: in a word, with wet collodion we can always obtain films of appropriate thickness and opacity; but in dry collodion things are quite different.

Numerous experiments have taught me, 1st, that there is a great difference between the two cases mentioned above; 2nd, that the collodion exclusively applicable to the dry process with rosin, requires the conditions indicated in the second case, that is to say,—to succeed, we must choose a compound of collodion which contains *much* iodide and *little* gun-cotton. This is the whole secret of the composition of dry collodion with rosin, which yields constant results. Nevertheless, the control of the matter is not so very easy. Difficulties must often be overcome, which arise from *too great* a change in the proportions. If the proportion of iodides is *too great*, that of the gun-cotton becomes too little. In this case, the set film of collodion is not in a condition to contain all the iodide of silver upon leaving the nitrate bath; and it is especially in fixing the picture with cyanide of potassium that the greater part of the particles of reduced silver are carried away by the stream of water employed to wash away the fixing solution. The whole image disappears, while the film of collodion, properly so called, remains adhering to the glass plate. It is an easy matter to obviate this inconvenience; for nothing is wanting to this collodion but a little gun-cotton; thus by adding a quantity of plain collodion and taking a fresh picture, we perceive that the image resists the stream of washing water, after it is fixed, if the silver bath be of proper strength. Care must be taken to avoid too great an addition of plain collodion; for a film that is too opaque, on account of an excess of pyroxyline, always gives fogged pictures, notwithstanding the addition of rosin.

As stated above, chance may furnish us with just such a collodion as may require nothing but the addition of a small dose of rosin to yield pictures exempt from fogging.

I shall now proceed to give a summary of the method I practice, which is always successful.

The collodion must contain:—

Not too much Ether, 50 per cent.
Much alcohol.
Much iodide, (iodides of cadmium and of ammonium.)
Very little pyroxyline.
Ordinary rosin, 1 per cent.

A little water added to the collodion, or what amounts to the same thing, the employment of a non-absolute alcohol, is not objectionable, too great a quantity must however be avoided, manifested by little drops under the sensitized collodion-film.

It may be asked, if it is not possible to assign exact proportions in this formula; I reply, that the quantities required may be ascertained after taking a few pictures; besides, it should be remembered that all the operations of dry collodion suppose some familiarity with photographic phenomena, and suggest the total impossibility of giving absolute quantities; one collodion will require 1 per cent. of pyroxyline, another double that quantity; the same quantity of two different sorts of gun-cotton rarely yield a collodion of the same consistence.

The quantity of rosin varies between 1 and 2 per cent. However, it is my intention to make a quantitative analysis of dry collodion, in order to ascertain by analysis what will always be very difficult to discover by synthesis.

With regard to the silver bath, I have already stated that its richness in nitrate is of some importance: if the bath be too weak, the image will vanish in washing the film, even if the collodion consists of the proper proportion of iodide and pyroxyline.

Seven of nitrate appears to me the best proportion to 100 of water; then the addition of a few drops of acetic acid assures the transparency of the bath, otherwise it becomes dark in a few days.

Upon removing the plate from the silver bath it is immersed in rain-water, and then rinsed in a second bath, and put to dry in a dark place free from dust. One of the advantages of this method doubtless consists in the sensitiveness of the films. Thus the time of exposure is much less than usual, when operating with dry collodion, dextrine, gelatine, or tannin.

The time of exposure varies according to the more or less sensitive quality of the collodion; that which I am now using requires thirty seconds in the sunshine, with a compound objective; with an half-inch diaphragm, a minute is required. This shows that the sensitiveness of the plates is sufficient for all ordinary purposes. I have also made some experiments to ascertain how long plates thus prepared will retain their sensitiveness without losing any of their good qualities. I have found that at the expiration of nine days they gave as good pictures as on the first day. Upon operating with the same collodion in a wet state, in the usual manner, the exposure required is the same, but the image is frequently rather weak. By this we perceive that my collodion, of itself, is not very sensitive, and perhaps the dry process may be accelerated by selecting a collodion which gives a negative picture more quickly, but I have not yet made the experiment.

After the exposure of the dry plate, we may take a reasonable time to develop the picture, sooner or later; but if much time be allowed to elapse, we shall not succeed without immersing the plate in the nitrate bath, and leaving it there until the last bubble of air adhering to the plate has disappeared from the film. These bubbles may be removed sooner by taking out the plate and blowing upon it.

The image is developed by pyrogallic acid; the solution must not be too strong. The Abbé Despratz has recommended the development of the image to be effected by immersing the entire plate in a dish containing the developing solution, to avoid stains occurring at the spots where the developing solution is poured on. The image soon appears and goes on developing until it reaches the desired condition of strength. The developing is then stopped by washing the film in ordinary water, and fixing it with cyanide of potassium. When it is ascertained that all the iodide is dissolved, by examining the opposite side of the plate, it is rinsed in plenty of water, dried and varnished.

Such are the manipulations of a method which is invariably successful. It has been surprising to me that the rosin dry process has not been more generally adopted; and I conclude the reason to be the difficulty in arriving at the most suitable proportions. That difficulty I feel happy in having solved, and if the details given above contribute to the success of other operators, I shall congratulate myself upon having published them.—*Cosmos.*

Scientific Gossip.

Photographers who are accustomed to employ the term "pure" in connection with their chemicals, and who fancy that that word stands for a property which is not difficult to secure, and when secured in any substance may be preserved indefinitely, will read with interest an account of the difficulties met with by one of the first analytical chemists in Europe, M. Stas, in his endeavour to procure pure chemicals for certain researches on the atomic weights.

In our chapters on "Photographic Chemicals" we have already treated of some of these bodies before, and have given the means best known at the time for procuring them in a state of purity. These experiments of M. Stas' will show that *chemical* purity even surpasses the high standard demanded for photographic purity, and may perhaps serve to urge amateurs on to seek a still higher standard than they are now in the habit of employing. In chemistry there is no such thing as absolute purity; the utmost that we can ever hope to effect is to reduce the contaminating elements down to the minimum; but what that minimum should be must depend upon the requirements of the the individual operator. Doubtless, when the science becomes more refined in its accuracy, and when, as must some day be the case, processes of almost fabulous rapidity and sensitiveness are in constant use, as superior in quickness to collodion as that is to calotype, it will be found that the great reason why perfection was not sooner attained was that we only took account of impurities in our chemicals when they amounted to thousandths and neglected the millionths.

We have already given the most approved methods of obtaining water and the common acids in a high state of chemical purity. At the time we wrote the processes given were the best known; it can give no better idea of the rapid strides which chemical science is now making than to compare the plans formerly recommended with those now adopted by M. Stas. By his researches he has raised the standard of purity in all the laboratories in Europe, and photographers as well as chemists cannot fail to benefit largely by the improved appliances placed at the service of manufacturers. Speaking of water—that first necessary for the photographer—the following plan is necessary to obtain it in a state of purity. It must be twice distilled, the second time being condensed in a platinum refrigerator, and not allowing the liquid to boil violently. When freshly prepared, this yields a liquid which, upon evaporation or dryness in a platinum vessel, either covered or exposed to the air, leaves no residue whatever. This then is the test for distilled water; and for our own part we must admit that we have never yet found any water of commerce that would stand it. This same distilled water, however, after having been kept for some days in a platinum or porcelain vessel, and then evaporated, leaves a very appreciable brownish yellow residue, which burns away completely at a red heat in the air. Distilled water, which would volatilise completely in a covered or open vessel, if acidulated with pure hydrochloric or nitric acid, then leaves when evaporated in a covered or open vessel, a yellow residue. It is therefore proved that ordinary distilled water, even if prepared with all possible care, contains volatile organic matter, which after a certain time becomes spontaneously fixed, and becomes instantly so under the influence of nitric or hydrochloric acid.

It is therefore necessary, if the presence of this organic matter in distilled water is objectionable, (and in photography it is certainly most hurtful,) to pass the vapour at the first distillation through a long copper tube, luted with clay and sand, completely filled with oxidised copper turnings, bent in a zig-zag manner, and heated to a full red heat in a furnace. The water resulting from the condensation of this vapour must be distilled a second time with care, and condensed in a platinum refrigerator. This refrigerator is a long platinum tube, soldered with gold, bent in the form of a syphon, and employed in a manufactory to condense sulphuric acid vapours. Water prepared in this manner may really be called pure: after keeping, or immediately, if submitted to evaporation by itself, or after acidulating with nitric acid, always volatilizes in a covered vessel, without leaving any trace of residue.

Pure water having been obtained, the next step was to get pure hydrochloric acid. This was effected by taking the so-called pure acid of commerce, and boiling it, conducting the vapour by means of a Bohemian glass tube, into some of the previously purified water, contained in a covered platinum vessel. The acid thus obtained can be evaporated to dryness in a platinum retort, without leaving the least trace of residue. If, however, the evaporation be effected in an open vessel, the matters floating about in the air are always fixed by the acid, and then the purest article will leave a yellow residue, in which iron is often found. It is thus seen that the method for ascertaining the purity of hydrochloric acid, viz. evaporating to dryness in an open vessel, is fallacious; and will always show the presence of impurities, whether pre-existing in the acid or not.

The next acid which M. Stas attempted to procure pure, was nitric acid. This was a matter of more difficulty. The commercial "pure" acid, sp. gr. 1·500 was distilled until the condensed product contained no chlorine. To test for this element, the acid must be previously mixed with four or five times its volume of water. Indeed an acid at its maximum of concentration can contain traces of chlorine without being rendered turbid by nitrate of silver solution. This is easily seen by adding nitrate of silver, to pure water and then mixing a few drops of this solution with strong nitric acid, which is known to contain traces of chlorine. The acid will remain clear, but by adding to it the remainder of the water, the liquid will be seen to be decidedly turbid. When the absence of chlorine in the distilled acid is clearly ascertained, it is to be twice re-distilled, and preserved from the air in well-stoppered glass bottles. This acid even now leaves a trace of residue, to remove which it is necessary to distil it a third time in a large platinum retort, employing a globe of Bohemian glass as a receiver. Moreover, this acid must always be used immediately after its preparation. As a test of purity, a whole litre can be evaporated down to dryness in a platinum retort, without leaving the slightest residue, provided its vapour is kept from all contact with air. In evaporating acids down with free access of air there is always left a more or less appreciable yellow residue, just as we have seen in the case of water acidulated with acids. M. Stas concludes from this that the impurities found by most chemists in acids, do not always pre-exist there, but have been communicated to them by the air having free access to them during the assay. He, therefore, recommends in testing acids, that the assays should always be performed in platinum retorts fitted tightly to Bohemian glass receivers (common glass being acted on by acids as well as by pure water); and that all evaporations of acid liquids should be performed in close vessels so as to prevent the air from penetrating into the interior of the vessel containing the liquid which is undergoing evaporation.

A specimen of glass has been forwarded to us by W. G. G. for examination in the spectroscope. It is an orange glass, rather dark, but not so deep as some which we have met with. It cuts off the rays above the line F very perfectly, and almost completely the rays between E and F. It is, therefore, quite opaque to the blue, indigo, violet, and invisible rays (those which act upon iodide of silver) and almost opaque to the higher green rays to which bromide of silver is sensitive in addition to the above. This glass is so nearly perfect that we should not hesitate to glaze our dark-room with it provided no great amount of light fell upon it.

DEVELOPING WITHOUT FREE NITRATE OF SILVER.

BY G. WHARTON SIMPSON.*

It has been a commonly received opinion amongst the majority of photographers, that the presence of free nitrate of silver was a necessary condition to the development of the latent image produced by light on the sensitive collodion plate. Theoretically, it has been held by some, that the presence of any two of the generally used salts of silver, would ensure the conditions necessary to development; but practically, the presence of the free nitrate has generally been regarded as an indispensable condition both in dry and wet processes.

I wish to call attention to a method of development likely to prove of the greatest possible importance in dry-plate photography, which involves the negation of this condition. My attention was first called to the subject in a communication received from Mr. Mudd, whose collodio-albumen pictures are generally acknowledged to be amongst the very finest specimens of dry-plate photography.

It is only right to add, that Mr. Mudd gives the *entire* credit of the suggestion to his assistant Mr. Wardley. The method of development referred to, consists in the application to the exposed collodio-albumen plate of a solution of pyrogallic acid, without either acetic or citric acid, and without any nitrate of silver; the strength mentioned by Mr. Mudd, is two or three grains to the ounce, but I believe the strength for this purpose is comparatively unimportant.

Contrary to what might be expected, the image rapidly develops very perfectly. When all the detail is fully out, the usual developing solution of pyrogallic acid, and citric acid, with a little nitrate of silver solution, is applied and the desired amount of intensity by this means obtained.

Having been struck with the manifest advantages of such a process, and having subsequently an opportunity of witnessing its simplicity and convenience in Mr. Mudd's hands, I was anxious to ascertain whether it was equally applicable to other dry processes. I have accordingly tried it on dry plates, by a variety of processes besides the collodio-albumen. I have tried it on Fothergill plates prepared by different persons; on tannin plates, and on Dr. Hill Norris's extra sensitive dry plates.

Mr. Mudd, in a conversation I had with him on the subject, expressed an opinion that notwithstanding his plates received a very thorough washing after their final sensitizing, some trace of free nitrate must be left, sufficient to aid development. I was led in my experiments with the plate referred—especially in the Dr. Hill Norris plates, which it is understood are entirely deprived of free nitrate of silver—to believe that development might be effected without any free nitrate whatever. In every instance I obtained an image more or less perfect on the application of pyrogallic acid alone. In order to test the matter still further, I excited a plate and proceeded very carefully to remove all free silver. I washed it in several changes of common water, and finally placed it in a dish containing a strong solution of chloride of ammonium, leaving it there for about a quarter of an hour. I now washed it again very thoroughly, using several quarts of water. Having taken every pains by washing, and the use of chloride to remove all free nitrate of silver, I exposed the plate and then developed with the solution of pyrogallic acid with silver or acetic acid. In a minute or two a very perfect, but very thin image was fully developed. On applying the usual developer and silver, the image intensified satisfactorily. I think from this it may be fairly assumed that the principle is applicable to dry plates prepared by any process, no matter what pains may have been used to remove all traces of free nitrate. The collodion I used was prepared with a bromide as well as an iodide. What the result would be with a simply iodized collodion I have not had time to try; neither have I had an opportunity of trying the salts of iron as a developer under the same circumstances.

In referring to the advantages of such a process, I think they must be very apparent. One of the most common faults of dry plate negatives is hardness: this arises doubtless from two causes; the first being a common tendency, especially in beginners, to under-expose their plates. But by far the most fruitful cause is the difficulty of determining, under all circumstances, the exact amount of silver to be added to the developer, so as to secure the proper harmony between the process of development in the film, and that reduction of silver upon it, by which intensity is obtained. If it so happen that prolonged development is necessary to bring out all the detail, it unfortunately happens that accumulation of deposit on the high lights, burying all the delicate half-tone immediately adjoining them, is at the same time going forward. If the development be stopped in time to save the lights and the lighter shadows, it frequently happens that much of the detail in the darker parts of the shadows is not brought out. The issue in either case is the absence of that delicacy, softness, and harmony of detail, necessary to constitute a good picture.

In the process I have been describing, development proper is effected before the accumulation of intensity begins; the attention is devoted to one thing at a time, and facility afforded for having each part of the process under complete control. The value of the principle, or at least a partial application of it, is essentially recognised by Major Russell, who makes every provision, in his instructions for the tannin process, for the use of a very small quantity of silver until the image is fully out, and the use of a larger portion to give density; but in no case that I know of, before Mr. Mudd's communication, was the possibility and value of developing without any addition of silver, hinted at.

I may add a word or two in regard to the use of hot developing solutions. How far these can be used with advantage in any process except the albumen or collodio-albumen, I cannot say. In regard to its value with the latter, I can speak in the highest terms. In some cases where I have used it, perfectly detailed pictures have been secured with one-fourth of the exposure which would have been otherwise necessary. The mode in which I applied the heat was simply by using hot water first to moisten the plate, and then applying a hot solution of pyrogallic acid without free silver or acid, until all the detail appeared, and then intensifying with the usual developer and silver without heat. As one of the most satisfactory illustrations of the principle, I may call attention to some of Mr. Mudd's recent pictures, which I have present. In one picture, 11 + 9, you will see natural clouds perfectly secured. This was taken on a collodio-albumen plate, with a lens of fourteen inches focus, and a half-inch stop, in thirty seconds.

My especial object is to call the attention of dry plate photographers, of whom, I know, we have many belonging to this society, to this method, so that its applicability to their various processes may be fairly tested. If it prove as useful as I hope, I think it will be hailed by all as a most decided step in the right direction.

A FEW NOTES ON DRY PLATE PROCESSES AT HOME AND ABROAD.

BY W. J. C. MOENS.*

I think it is pretty generally admitted that all dry-plate processes are more or less uncertain in their results. I do

* Read at the meeting of the North London Photographic Association, on the evening of Wednesday, October 23, 1861.

* Read at a meeting of the North London Photographic Associaion, October 23, 1861.

not mean by this to say that good pictures cannot be taken, even by the most unpopular of them; but the failures which even the most careful photographer is sure to meet with from time to time, always causes him to look with great anxiety to the period when he shall develop the plates which he has exposed with so much care and trouble, and on the success of which he probably has looked forward to for months. This is taking the case of amateurs, with professionals it is even worse, they hardly dare to leave an order to the uncertainty of a dry plate. The effect of this is that dry photography has gradually been deserted by most of its former adherents, for the simple reason that they cannot afford to lose a large per centage of their exposures. I cannot help thinking that the chief cause of most of their failures, which commence at stains and end at blisters, is the humidity of our climate, which causes the plates to be more or less damp from the time of cleaning them till they are developed. In France and Italy, where wet collodion is the exception and dry plates are the rule, you do not find these failures: there, especially in Italy, the air, generally speaking, is so dry that gelatine takes the place of our gum and resin varnishes.

Simple albumen and collodio-albumen are the two dry processes most generally followed. Those splendid views of the French Cathedral, the ruins of ancient Rome, and the statues in the various museums, are nearly all taken by the former. Collodio-albumen is more used for stereographs. There is one thing we must remember in speaking of our neighbours' use of dry-plates: their views are almost without exception, architectural; trees are studiously avoided, and the skies painted out; all which makes their work more easy. I purpose now to give you a few hints I picked up from French, Italian, and German photographers, as regards their method of working these two processes; generally speaking, our brethren abroad make the greatest mysteries of the simplest matters, and are very far from being communicative.

They are very particular in drying, with heat, their plates before coating them; neglecting to do this is the chief reason of blisters, and is a precaution which should never be neglected; very often, instead of mixing an iodide with the albumen, they subject the plate to the fumes of iodine. The large plates are coated by spinning the plate, fixed on a holder made for the purpose, and pouring the albumen on the centre, it soon reaches every corner, and the excess is driven off by the motion imparted to the plate. It is carefully dried in a horizontal position, with a board between each plate. The nitrate baths are generally flat trays of gutta-percha, thereby avoiding the enormous vertical bath that would be necessary for the large plates used.

The development is effected by gallic acid, and conducted as follows:—The plate is levelled on a stand, and a saturated solution of gallic acid, a *few days old*, is poured on, and spread over by means of a piece of clean blotting-paper. This is left on for a few minutes, in order to thoroughly moisten the film, then poured off, and an equal quantity of nitrate of silver, of from fifteen to twenty grains to the ounce, spread over in the same manner, this quickly brings out all the detail, when the silver solution is poured off into the gallic acid first used, this is found desirable in order to obtain the required density, taking care not to make them too thick. This is a powerful, safe, and quick method of development, and you can attend to several plates at the same time. Should a plate be under-exposed, the flame of a spirit lamp, carefully passed backwards and forwards under the plate, will often aid the required details to make their appearance, it is very necessary to have the developing glasses very clean each time.

I will now give the details of a collodio-albumen process used by Mr. Schartzchild, a celebrated German photographer I met at Palermo, *he* took quite a pleasure in explaining it. And not only explaining, for he went through the whole preparation and development of the plates in my presence, in order that he might be thoroughly understood. I saw a great number of his negatives, and they were all first-class: he said he seldom or ever had a failure. Most of his pictures were on glasses about seven by six and a-half inches, so as to allow of two negatives being taken of each subject. I will now give the formula:—

The plate is first coated with old collodion, containing a little free iodine, and sensitized in a neutral bath of nitrate of silver, about twenty-five grains to the ounce; it is then washed in two or three changes of distilled water, and drained; then carefully covered in one wave with the following solution of albumen, which is run off, and then covered again for about half-a-minute with fresh solution, when it is reared up to dry thoroughly:—

Albumen	4 ounces.
Water	½ ounce.
Iodide of potassium	24 grains.
Gum arabic	30 ,,
Ammonia	45 minims.

The plates in this condition may be stored for use. When wanted they are re-sensitized in an aceto-nitrate bath—

Silver	1 ounce	Saturated with iodide of potassium before adding the acetic acid—
Water	10 ounces	
Acetic acid...	1 ounce	

and wash as before. The exposure in sunshine is about two minutes for stereo negatives, and developed in the same way as the albumen plates; clear with hypo, for cyanide is apt to raise the film in wrinkles. I think that a bromide and chloride added to the albumen would render the plate more sensitive to dark green and red rays.

I obtained some very good pictures when abroad by this process, but have not tried it since I returned, always using wet collodion in preference; but I can strongly recommend it to lovers of dry plates, having seen magnificent pictures taken by it in Egypt, Turkey, Syria, and all the southern countries of Europe. The method of using gallic acid as a rapid developer is, I believe, novel here. I have seen several pictures treated so, and with great success.

Critical Notices.

A MANUAL OF ARTISTIC COLOURING AS APPLIED TO PHOTOGRAPHS. A Practical Guide to Artists and Photographers. By Alfred H. Wall. London: Thomas Piper, Photographic News Office.

Perhaps we cannot do better at the outset of a notice of this work than quote its title at length, in order to furnish some idea of its comprehensive purpose and character. It purports to be "A Manual of Artistic Colouring as Applied to Photographs: a Practical Guide to Artists and Photographers. Containing clear, simple, and complete instructions for colouring photographs on glass, paper, ivory, and canvas, with crayon, powder, oil and water colours; with chapters on the proper lighting, posing, and artistic treatment generally of photographic portraits; and on colouring photographic landscapes." Until photographs can be produced in natural colours—if ever that desirable but improbable consummation be reached—the aid of the painter must be in demand in order to give to portraits their full value as likenesses, and endow them with that charm of colour which Opie so beautifully styles "the sunshine of art, which clothes poverty in smiles, and renders the prospect of barrenness itself agreeable, while it heightens the interest and doubles the charms of beauty." It can scarcely be necessary, we apprehend, to attempt for one moment to enforce the importance and value of colour in any branch of pictorial art, and pre-eminently in portraiture. It is a thing generally at once admitted. The universal love of colour at once proves its importance as a pictorial element. The first proof given by the uncultured savage of his perception of the beautiful is manifested in his appreciation of colour. The last effort of the most highly cultivated painter is to excel in colour. We have heard some exclaim, it is true, that they would prefer a good uncoloured photograph to a bad coloured one, but that is simply an argument for the selection of goodness in preference to badness, and, we apprehend that the most vehement admirers of the monochrome, in choosing between a coloured and uncoloured specimen, each of equal excellence in its kind, would unhesitatingly select that in which beauty of colour was added to truth of form.

Presuming, then, that the value and importance of colour are admitted, we have simply to add that this is one of the very best books yet offered to the amateur or professional colourist. Several manuals of photographic colouring have already been issued, and some of them possessing much excellence; but none of them possessed such a claim to comprehensiveness and completeness as the one before us. A portion of the matter appeared in the columns of a contemporary as lessons in colouring. During the progress of these lessons, which spread over a period of nearly two years, the author was in constant communication with the students who were profiting by his lessons. He thus gained an immense fund of experience as to the varied form of difficulties experienced by the tyro in this branch of art, and was thus enabled in re-writing and extending his instruction, to meet the precise wants, and anticipate each stumbling block, which can occur in the practice of future learners. The result is a fulness of detail on points important to the student, scarcely likely under any other circumstances to have been suggested.

Our readers are already very familiar with Mr. Wall as a writer on the art aspects of photography. We here have the opportunity of assuring them that he is even more able with the pencil than the pen; a thoroughly experienced and excellent painter, and that in writing on the colouring of photographs, he is not dealing with the matter theoretically, and offering crude suggestions, but that, like Mr. Guppy, he speaks "from the deep wells of his experience." His teachings are those of a practical man who has done, and is daily engaged in doing, that of which he writes. The following extract from his introductory chapter will serve at once to illustrate the style, and explain something of the purpose of the book.

"In publishing these instructions I have endeavoured to combine the principle of harmonious colouring with the more mechanical rules, believing that the theory and practice of any art should always travel hand in hand. I have tried to avoid being too technical, and have not been afraid to enter into descriptions and explanations of such simple matters as are generally left unexplained by writers who, while endeavouring to teach the elements of colouring to those who desire to learn, yet, address their readers as if they had mastered all the theories and technicalities of the art, and only required a little of that knowledge which they themselves had gleaned from their own absolute practice.

"Such practitioners of our elegant arts as have never before thought much on the subject of photographic colouring will, perhaps, be surprised to find the amount of artistic culture and knowledge essential to its higher order of excellence; and may be induced to look upon this pursuit with more interest and respect, even if they do not direct their own efforts into the same channel. Many amateurs, who vainly endeavour—with their limited opportunities—to grasp the power of representing both form and colour, would do well to take up earnestly the study of the latter, leaving the former to the unerring fidelity of the camera, as used either by themselves or by some *artistic* photographer. The world of colouring is full of loveliness and poetry, and opens a wide field to the ambitious artist; while there is nothing more illegitimate in painting upon a good photograph than there was in the practice of Leonardo da Vinci, Rubens, Titian, Raphael, Guido, Fra Botelemo, and numerous other eminent masters, who painted upon the abozzo, or sketch in dead colour, which, to all intents and purposes, was neither more nor less than a warm-toned photograph.

"Unfortunately, photographic colouring has, to sadly too great an extent, fallen into the hands of mechanical daubers, employed because they work cheaply, and "yclept *print colourers*;" whose gaudy inartistic colouring, and crude, raw, and hard style has brought the art into no little disrepute; by which, also, it has been sometimes most unfairly judged. The technical phrase for such "colourists" (?) is "paper-stainers." They are the greatest enemies both to photography and photographic colouring; for of this I am sure, directly any art becomes degraded in public estimation, it speedily sinks even below the level assigned to it.

"Coloured photographs occupy an undeservedly questionable situation: the artist curls his lip at them, because, as *he* says, they are not paintings; and the photographer sneers at them, because, as *he* says, they are not photographs. They are peremptorily denied admittance to galleries of paintings, and it is continuously and frequently urged that they should not be admitted to photographic exhibitions. Why, then, is this poor art to be an outcast among its brethren, unacknowledged and denounced by both artists and photographers?

"The photographer admits the beauty of colour in a painting, and admires it as warmly as need be. The artist admits the truthfulness of the photograph, and admires its wondrous delicacy of detail, faithfulness of drawing, and perfection of chiaroscuro just as warmly. Why then, should an art which combines the truth of the one with the loveliness of the other, be thus unsparingly denounced by these two important classes.

"Unity is strength, and the beautiful can have no better mate than the truthful. Let the scientific man of the camera, and the tasteful son of the palette, throw aside all their childish jealousies, and combine their efforts for the production of works valuable, both for fidelity to nature and for artistic merit. The best interests of photography are served by advocating its union with art, in demanding for it a much higher standard of worth than it can ever claim as a simple mechanical acquirement, calling for no greater intellectual effort than that implied by carefulness and manipulatory skill; to which condition there are those who now labour, mischievously, or ignorantly, to reduce it.

"To those who are desirous of adopting photographic colouring as a profession, I would urge the following considerations:—

"1st. The market is full of inferior colourists, who jostle and elbow each other at every turn; and these are working at such absurdly low prices that a decent livelihood is, for such, almost out of the question.

"2nd. Beware of a class of advertising quacks, who pretend to teach the art perfectly in four or six lessons. Several young persons of either sex, anxious to secure a genteel if humble livelihood, have to my personal knowledge been induced by such deceptive advertisements to expend their little all in procuring materials and lessons, and in supporting themselves while studying only to find, at the expiration of the lessons, that, while quite unable to earn a shilling by the information thus acquired, and without means of support, they were placed at the mercy of their friends and acquaintances, or of the cold hard world. These contemptible quacks may, or may not, contemplate such serious consequences; but I speak feelingly, knowing how, in one case, a most respectable young lady was thus victimized, and plunged into the most terrible dangers and difficulties.

"3rd. When practising the art professionally, avoid an error which has induced some of my professional acquaintances to tease me with remonstrances and croakings of a very illiberal and ungenerous nature during the progress of this work. Such information and instructions as mine do not tend to decrease the value of a profession by increasing the number of its professors; but, by improving the judgment and elevating the standard of excellence among photographers, really serves the profession, by driving from the field the inferior colourists, now so extensively employed, and increasing the demand for real artistic excellence. The most talented colourist will labour in vain if his patrons are not qualified to appreciate his powers.

"To show both photographers and colourists the advantage of earnest study, and the acquirement of real excellence; to instruct so that the humblest may acquire a power proportionate to his or her ability and perseverance, and to raise my art in the estimation of as large a circle of readers as I may have the good fortune to command, constitute my chief aim in writing these pages."

In conclusion, we cannot forbear a word or two on the "getting up" of the work. It is richly bound in mauve-coloured cloth, gilt, bevelled boards, and gilt edges, admirably printed on excellent paper, and altogether the most handsomely got-up book which has yet been issued in connection with any branch of the photographic art.

Photographic Tourist.

MY FIRST PHOTOGRAPHIC TOUR.*

Mere written words cannot describe the deep-felt, earnest gratitude with which our full hearts thanked Providence for the timely aid afforded in the sale of this picture; it came like a stout cable to the desperate grip of the drowning; like a sudden restoration of healthy life to the bed-ridden sick, or a broad strong shield thrust swiftly between us and a descending death-blow.

Leaving Chelmsford, the last memories we carried away from this little town, were those of its races. Great was the bustle, extensive indeed the preparations, and by no means small the dignified importance with which the Chelmsfordian natives ushered in this great event. All the previous day a long panorama of travelling shows, conjurers, gipsies, dancing girls, musicians, performing dogs, &c., came passing through the place, and towards evening an immense sensation was created by the advent of two short sturdy-limbed men, with wen-like joints, in pink fleshings, and scanty, well-worn velvet trunks, heavily bespangled, having bracelets to match, who rode sternly in with folded arms upon two tame "trained steeds," arrayed in theatrical finery as worn and shabby as that of their wonderful masters. But these were only shadows to the coming event of the morrow, when Sunday attire made glad the weekday sun, when every vehicle of every kind was furbished or mended up for use or hire, when small but majestic, scrupulously clean, and brightly smart jockeys were visible, the admired of all beholders, smiling condescendingly in conversation with the great, but not above bestowing a monosyllable or two upon the awe-hushed, gaping small; and when coach after coach-load of excited sport-seekers were borne in clouds of dust from the town amidst the wild hurraying of the frantic juveniles, until the last having disappeared silence again reigned supreme, and the poor little place seemed even more lonely and deserted than ever. But towards evening back again came all the uproarious noise, and all the excited crowd, with the addition of brass bands, and barrel organs, and violins, and singing and shouting, and screaming, &c., until the inns grew full and overflowed with drunken revellers, for whose coppers the home-made niggers banged and twanged, and rattled and jingled, and the shabby touter outside the patched and tattered circular booth of the equestrians bawled, hoarsely, "Hi! hi! hi! hi! this way! this way! to the riders! the riders! hi! hi! hi! hi!" and we, in the midst of all, bade all adieu, and went our way to Colchester.

We started for a stroll through this proverbially loyal town the morning after our arrival therein, and I was first pleased to see the numerous picturesque old houses, with their high gable roofs, projecting stories and uncovered timbers. How strangely familiar—even when they are something quite new to our eyes—these old houses always appear; they come to us like good old musical airs, old-fashioned pieces of furniture, or any other things of ancient days, which judged by ordinary reasoning, should be novel and strange, but which are, nevertheless, so mysteriously homely and familiar. From some such cause, this old town being full of remnants of the past, seemed like an old friend long neglected, rather than a new one never seen before.

I was next attracted by the novelty presented in a lowly little, old church, which, thrusting a clock out over the pavement of the High-street, from a stumpy, ivy-grown, dwarf of a tower, stood with its one half in complete ruin. This, I found, was called St. Nicholas, and the portion in ruin had fallen many years ago, and had been left ever since just as it then appeared, save that the creeping ivy had gradually cloaked its crumbling walls, and tall mocking weeds now flaunted it bravely above their roofless heads.* Turning round by this relic, and bearing to the left, I was soon afterwards betrayed into an exclamation of delight by seeing, close beside the shabby, ill-supported theatre, the grand old picturesque ruins of some rare old priory, called, as I soon learned, St. Botolph's, or, as my informant said, "St. Bulph's." This is a great treat for the artist or architectural antiquary. The massive remnants of the once stately and richly decorated walls stand rugged and rock-like, half clothed in luxurious ivy wreaths, and bearing on their broad tops a thick crop of tall, waving grasses, and gracefully bending weeds; the shattered pillars rear themselves grimly against Time, the conqueror, and perish slowly but unshrinkingly like warriors disdaining flight; while the broken and crumbling relics of the ancient sculptor's chisel, showing here and there in defaced and battered fragments, now seem far more closely allied to nature than to art. I got a capital view, some few days after, of the ruins from a post near the iron gate by which you obtain admittance to inspect them, obtaining, in my picture, the elaborately decorated gateway of the once magnificent west front, and the tall, circular arched pillars at the sides. The building dates from the reign of Henry the First, was shorn of its importance by the Reformation, and fell, with so many other things of joy and beauty, before the morbid passions of the strong red-handed Puritans during that that terrible Civil War, in which this staunch old town displayed so well its—let me see—what shall we say? its unswerving loyalty and honest truth? or, its stupid prejudices and obstinate bigotry? Well, perhaps the age is not yet old enough to decide. But we are quite old enough to denounce the fanaticism which could thus destroy the records of our country's earliest and noblest aspirations, and lay in dust so many of the noblest works of that sweetest nurse and handmaid of all true religion—Art. Oh! Fanaticism and Bigotry, how have ye cursed the lands and their inhabitants, and what deadly instinctive enemies to Beauty have ye ever been, piling the most costly works of the Brush, the Chisel, and the Pen on one huge funeral pyre, as at Florence, battering down the stately fabrics raised by glowing reverence and love, as here in Colchester, or sternly denouncing the Drama, Music, and the Fine Arts in our own Ebenezer Tabernacles and Sectarian Meeting-houses.

My next point of interest was "The Castle," it stands to the north of the High Street, close behind the houses, and a sturdy old stronghold has it proved. Notwithstanding the power of increasing and advancing years, the assaults of war, and the attempts of those who were to it even stronger foes, who wanted the ground on which it stands to serve some meaner purpose, it still remains, obstinately defiant of both man and time. Strange tales of wild daring and frantic strife could these rugged walls unfold, of the havoc and destruction with which it was surrounded, when victorious Fairfax came at the head of his parliamentary army, and fumed, and chafed in spiteful bitterness, and futile rage about its strong towers for eleven tedious weeks: again and again repeating the desperate assault, and again and again retiring, baffled, and despairing from its well-defended flinty barriers. The dauntless loyalists surrendered at the expiration of that time, but not until the sick, weary, hollow-cheeked, and leaden-eyed defenders were completely worn out, and had no longer the smallest scrap of their jealously-hoarded food, nor cat, nor dog, nor horse, nor any dead or living thing which man could eat for life, remaining in their reach. I was never more interested than in reading the account of this protracted siege, and afterwards used to look with no small degree of sadness and interest, upon two small white stones beside the castle, which mark, it is said, the spots on which the king's good men and true—Sir Charles Lucas and Sir George Lisle—were shot to death immediately after surrendering, not to the Puritans, but to even a more cruel foe, starvation. The mound on which

* Continued from page 495.

† It makes a very good picture, and my daguerreotype of it never fails to awaken interest in all who see it.

the castle stands is said to be of Roman origin, and on the loftiest tower—in the place doubtless, where once floated the proudly defiant banner of the dethroned king—a goodly tree is growing. I secured, before leaving the town, two camera pictures of the castle, but was unable to get far enough from it to secure such a view as omitting a too conspicuous cabbage garden, I afterwards got with my pencil. A very picturesque effect, however, would result from taking it with your camera, stationed at the commencement of the lane which runs behind the castle, taking in the cottages on one side, and the trees on the other. I have since seen several paintings of the castle in which this view has been selected by the artists.

But the town of Colchester is a rich mine of interesting objects, and being only a short distance—about fifty miles—from London, can be easily reached by our metropolitan photographers; in fact, I do not know a place in which a more pleasing variety of views can be secured. No end of picturesque and beautiful spots exist in the town's immediate vicinity, and in the town itself a number of fine ruins, ancient churches, and old fashioned houses, will serve to fill worthily no small number of plates. St. John's Abbey gate is well worth taking among the rest.

LECTURE ON PHOTOGRAPHY.

BY CHARLES HEISH, F.C.S.

A LECTURE on photography was delivered on the evening of Tuesday the 22nd, at the Greenwich Literary and Scientific Institution, by C. Heish, Esq. The lecturer began by stating that it was not his intention to go into the manipulatory details of any particular process, but rather to endeavour to point out as far as they were known, the principles involved in the various processes, and to show how far the actions were strictly due to light, and how far to other and more ordinary chemical actions.

He then proceeded to point out that all chemical actions were divisible into two classes, one the combining of bodies together to form more complex substances, and the other, the decomposing of complex bodies into the more simple ones of which they were composed. The chemical action of light was no exception to this rule, it caused combinations, as an instance of which he mentioned the combining of chlorine and hydrogen when exposed to light, it caused decompositions, of which the blackening of salts of silver in light was an example, consisting as it did of the separation of the silver, wholly or partially from the substance with which it was combined in the salt.

He then said he thought he should best show how these principles had been applied to the production of pictures by the agency of light, by passing in review the various photographic processes, beginning with the first recorded observation on the action of light on chloride of silver by the alchemists. He next called attention to the observation of Scheele, that silver salts blackened more rapidly in the violet rays of the spectrum than in any other part, and having thrown a beam of electric light through a prism on to a white screen, pointed out the various parts of the spectrum, with its point of greatest action. He then gave a brief description of the various photographic processes previous to the discovery of Daguerre, exhibiting the production of a copy of a piece of black lace on paper prepared with chloride of silver, by means of the electric lamp. He then spoke of the Daguerreotype as the opening of a new era in photography, as it introduced the principle of combining the reducing action of light with that of ordinary chemical reducing agents. He then proceeded to show what was meant by a reducing action, taking as the most simple instance, the action of hydrogen on oxide of silver, and showing that though hydrogen might be passed over oxide of silver in the cold without producing any effect, that a slight elevation of temperature caused the hydrogen to combine with the oxygen, producing water, and leaving metallic silver in the form of a brilliant white powder. He then showed that one metal might act as a reducing agent to another, an instance of which was the action of mercury on nitrate in silver, in the production of the well-known "arbor Dianœ." Here was a simple action of substitution, the mercury combining with the nitric acid, and liberating the silver without any other agency than that of superior chemical affinity. In the daguerreotype plate the action was so far different, that the mercury could not reduce the iodide of silver until it had been acted on by light, that agent playing the same part with iodide of silver, in causing it to give up its iodine to mercury, that the heat did with oxide of silver, in causing it to give up its oxygen to hydrogen. He noticed that at first the white parts of a daguerreotype were thought to consist of globules of mercury, but subsequent investigation had shewn that they mainly consisted of reduced silver, the greater part of the mercury employed being found in the form of iodide in the fixing solution.

He then gave an account of the experiments of Rev. J. B. Reade and Mr. Talbot with gallic acid, which ended in the invention of the calotype process, and described the action of both gallic and pyrogallic acid as a reducing action, similar to that of the mercury on a Daguerreotype plate; indeed, by proper management, a Daguerreotype might be developed with gallic acid and a paper picture with mercury. He showed the reducing effect of pyrogallic acid in a solution of nitrate of silver, producing at once a black deposit of silver, which was, however, not the case with the iodide till it had been exposed to light. He pointed out the similarity of this action with that of the hydrogen in the tube of oxide of silver; indeed, the pyrogallic acid owed its power of reduction mainly to the large quantity of loosely combined hydrogen which it contained; and he showed that the black colour of the deposit was simply owing to its state of agregation, as a burnisher it became like polished silver. After describing the albumen and collodion processes, he proceeded to remark on the introduction of bromide of silver, both in Daguerreotype or other processes, and explained that its goo d effect was due to the fact, that while iodide of silver was affected only in the violet and blue parts of the spectrum. Bromide was also affected by the green and even slightly by the yellow. He then adverted to the fact of the action on iodide of silver being principally caused by the invisible rays beyond the spectrum, and exhibited a protograph of the spectrum on the screen in which the limbs of the visible spectrum were marked by lines drawn on the plate. He then said that he thought photographers had been too much led away by the superior sensibility of iodide of silver to these extra spectral rays, to neglect the study of other salts, forgetting that it is a representation of the *visible* rays that is really wanted. He then adverted to the fact that according to Senebin's old experiments, chloride of silver was affected by every part of the spectrum, being blackened as much in 20 minutes by the red rays as by the violet in 15 seconds; as far as he knew, no amount of exposure would make the red rays affect iodide of silver. To this fact he attributed the good which he himself had years ago pointed out to arise from a duo admixture of chloride with iodide and bromide in taking objects of various colours. He then remarked that the only successful attempt to produce the natural colours by photography had been that of Becquerel, who employed a peculiarly prepared chloride of silver, and had produced brilliantly coloured copies of the solar spectrum. The exposure required was too long to admit of this procsss being applied to ordinary photography; but if ever coloured photographs are to be produced, it must be by the use of substances applied by the coloured and not the extra spectral rays.

The difference between positive and negative photographs was exhibited by throwing on the screen enlarged images from to explain glass negatives and transparent positives.

In conclusion, the lecturer said he had intended to speak of positive printing and toning, but having already detained his auditors nearly two hours it was impossible; but he might remark that the same principles which he had been endeavouring to explain were involved in both these processes.

He would now only ask them to examine the specimens on the wall behind him. Those illustrating calotype being by Mr Turner, and those on wax paper by himself, while, for the extremely beautiful specimens of wet collodion landscapes, he was indebted to his friend Mr. Heath.

Proceedings of Societies.

NORTH LONDON PHOTOGRAPHIC ASSOCIATION.

THE usual monthly meeting of this association was held at Myddelton Hall on the evening of Wednesday, October 23rd. G. SHADBOLT, Esq., in the chair.

The minutes of a previous meeting having been read and confirmed, Messrs. T. Ross, and T. F. M. Ingall were elected members of the Society.

A letter was read from the Bradford Photographic Society, intimating their intention of holding a Photographic Exhibition, and asking for the co-operation of this society. It was resolved that members be asked to aid, as far as possible, in their individual capacity, the Bradford Exhibition. The North London Society, in its corporate capacity, had not power to do more than express interest in, and approval of, the efforts of the Bradford Society to advance the art.

Mr. G. Wharton Simpson then read a paper on Developing without Free Nitrate of Silver (see p. 518). Some very fine specimens by Mr. Mudd illustrating the method of development were examined, and much admired.

Mr. Seeley remarked that he recently found the image visible in a tannin plate after exposure, but before developing at all. The image became apparent immediately on wetting the plate.

The Chairman remarked that the circumstance was not uncommon with tannin plates where the exposure had been long. It occurred also with plates prepared with honey.

Mr. Seeley thought that a deposit of silver was necessary to form the image.

Mr. Simpson remarked that the reduction of the salts of silver in the film formed the image. The purpose of free nitrate was to give intensity. The circumstance of an image being apparent before developing, sometimes occurred with long exposures in the collodio-albumen process, and in others where any reducing agent was in combination with the silver.

Mr. Seeley thought it would be difficult in hot development to maintain the same temperature all the time of development.

Mr. Simpson said that it was unnecessary. He simply wetted the plate first with hot water, and then applied the hot solution. If that cooled before the detail was out, he applied more. The temperature might be about 150° more or less. How far it would answer in the wet process, or other dry processes, he could not say, as he had only tried it with collodio-albumen plates, from which the surface deposit, it was apt to cause, could be easily removed.

The Chairman observed that the subject of the paper was one of considerable practical importance in connection with dry-plate photography. With regard to the rationale of the matter there were two or three things struck him, which he before made some memoranda regarding, and he might now refer to them. It would be noticed that the preparation of all dry plates secured the presence of organic matter in combination with the silver, and this could be reduced without any development whatever. In the collodio-albumen, and Fothergill, there was albumen, in Major Russell's process, tannin, in Dr. Hill Norris's, gelatine. There was one point in Mr. Simpson's experiments which suggested to his mind that something more was present in the latter than gelatine. The readiness with which an image was formed by the developer without free nitrate, suggested that they were treated with some other form of organic matter prior to being covered with gelatine. It had been suggested that serum of milk was used. Then regarding the next experiment of Mr. Simpson's, in which there where only bromide, iodide, and chloride of silver present. Of course some traces of chloride would be present, however carefully the plate might be washed; and it was well known that the chloride could be reduced, and the same with the bromide. To set the question at rest whether an image could be developed by the reduction of iodide of silver alone, without the presence of any other reducible salt of silver, it would be necessary to prepare a plate with a simply iodized collodion, after exciting, wash it with a solution of an iodide, and after exposing a plate so prepared, endeavour to develop a picture without the presence of another salt of silver.

Mr. Simpson thought this experiment would scarcely meet the case. He had used a chloride to get rid of the free nitrate, because that was the mode usually adopted in dry processes where it was thought desirable to ensure the absence of free nitrate, and he wished to secure the same conditions. He had thought of the use of an iodide; but he did not think the experiment would be a fair one, seeing that many excellent authorities held that iodide of silver alone, or iodide of silver plus an iodide, was insensible to light, and if the plate were insensible to light an image could not, of course, be developed with or without the presence of free nitrate. There was another conclusion drawn by the Chairman from one of the experiments stated in his paper, which perhaps it was desirable to correct. The Dr. Hil Norris plates had not developed readily without free silver, but very tardily, more so than those by any other process. The image appeared very slowly and was of a very thin and feeble character when it did appear, so that there was nothing which necessarily suggested any organic combination with the silver.

The Chairman could give a distinct denial to the idea that iodide of silver was insensitive to light, as he had prepared a plate so, exposed it to light, and obtained a picture.

Mr. Simpson had not himself tried that method with a collodion plate, although he had often tried an analogous experiment with the Daguerreotype plate, in which case he knew the iodide of silver to be capable of receiving an image.* It was, however, commonly held by authorities that iodide of silver alone, or with excess of an iodide was insensitive to light; and as his experiments had not been undertaken with any view to testing moot points of a theoretical character, but with a view to a direct practical bearing on the usual methods of preparing dry plates, he did not think it wise to convert the free nitrate into an iodide.

The Chairman must not be understood to be urging any objection. On the contrary, he thought the subject very important, and the practice highly desirable; but in all these cases it was very desirable not only to obtain a good result, but also to know the cause. The experiment he referred to he had published some years ago, when he was led to the experiment by the advice then given so commonly to expose the iodised calotype paper to sunlight. He had no doubt whatever of the sensibility of iodide of silver. He had indeed on occasion exposed one plate to three or four views. Having for some reason come to a conclusion that the picture on an exposed plate would not be satisfactory, he washed it with a little weak iodized water, which discharged the image, and rendered the plate sensitive to another impression, in the same manner as an exposed Daguerreotype plate was again rendered sensitive by exposure to the fumes of iodine.

Mr. Simpson might add that he had tried other experiments, which, though less conclusive, gave results decidedly opposed to general authority on the subject. Mr. Hardwich, for instance, in the theoretical part of his "Photographic Chemistry," stated the fact emphatically that free nitrate of silver was necessary to development, and suggested as an experiment in proof, that if an excited and exposed collodion plate were washed with distilled water, and then covered with the developing solution, no image would be produced until a little free nitrate were added. He had tried the experiment, and succeeded in obtaining an image, without adding the free nitrate.

The Chairman suggested that probably Mr. Hardwich tried the experiment with pyrogallic acid solution, containing acetic acid, and the restraining influence of the acid was sufficient under the circumstances to prevent development.

Mr. Hill intimated that he had had on one occasion developed without free silver some dry plates which were simply washed and dried without any preservative.

Mr. Simpson might just call attention to the advantages which hot development afforded for securing natural clouds. One of Mr. Mudd's specimens, now before the meeting, illustrated this. When the clouds appeared, the plate was washed, and the foreground forced with the hot solution. The experiment was very successful.

Mr. Moens then read a paper "On Dry Processes at Home and Abroad." (See p. 518.)

Mr. Hughes remarked that he thought he remembered Mr. Ackland mentioning a similar method of development to that referred to by Mr. Moens, in which after the application of pyrogallic acid, the development was continued by the addition of a large excess of silver solution.

The Chairman thought that though this, and the method described by Mr. Simpson appeared the very antipodes of each other; they were really similar in principle. The object was in both cases to bring the developing agent in contact with the smallest quantity of silver.

Mr. Seeley said that at the South Kensington Museum he believed they were in the habit of developing wherever the subject was difficult to bring out, with equal portions of a 1½-grain solution of pyrogallic acid, and of a 30-grain solution of nitrate of silver.

Mr. Hughes remarked, that in this case the extreme was

* We may here add that it is thought by some authorities that the Daguerreotype plate does not present an analogous case to pure iodide of silver when entirely isolated; as the metallic silver in immediate contact with the particles of iodide may play some part in the matter.

certainly obtained, and the maximum of silver was brought into contact with the developing agent.

The CHAIRMAN asked Mr. Moens what part the gum was intended to play which was introduced into the albumen.

Mr. MOENS believed it was thought to attach the film more firmly to the glass.

The CHAIRMAN thought the reverse. Some time ago the addition of sugar to the albumen had been recommended, with the view of making the dessicated albumen more permeable by the developing solution. Perhaps the gum might be supposed to have a similar effect.

Mr. HUGHES remarked, that the method just referred to by the Chairman was that known as the Whipple modificaton.

Mr. SEELEY asked if gum alone could not be used as a preservative, and what were the objections.

Mr. SIMPSON said it could be used, and was much admired by some. It did not keep well however, and was apt to stain and fog. The addition of citric acid in some degree modified these defects.

Mr. HOWE showed a series of negatives, which were described as produced by Mattheson's collodion developed by iron, without any subsequent intensifying.

Mr. HUGHES remarked that the circumstance pointed out as the especial advantage here was, what he should regard as the chief defect. The pre-eminent advantage which iron had as a developing agent over pyrogallic acid, was the fact that by its agency the whole of the detail in a picture could be developed without having obtained at the same time any sensible degree of intensity, thus leaving the negative in a condition to have just such a degree of intensity added, which might be judged desirable. Taking a common sense view of the matter, the operator had, in developing, two distinct objects. His primary object was to secure all the detail in his subject; that done, he had to give such density as might be required for printing. To the change in this respect, which had now become general, might be attributed, he conceived, the superior class of pictures which were now produced, as compared with those common when the processes of development and intensification were conducted in one operation. Wherever that was done, no matter what was the developing agent, there was danger of getting too much density in the high lights when the development was continued long enough to bring out detail in the deep shadows; or on the other hand, if development were stopped when the lights were just right, then there were masses of shadow without detail. There was a choice of evils; in either case the picture suffered. In the old method of pyro development these two processes were always going on at the same moment, and it was most difficult to hit the happy medium desired. The method, now used, of developing with iron, rendered all this easy. He had not been present at the commencement of the meeting, but he had no doubt his friend Simpson would have pointed out to them that Mr. Mudd's method of developing dry plates was based on the same principle, and this would at once explain how it was that his pictures were celebrated for softness and detail, although produced by a process which in other hands was noted for hardness. It was not a new thing to produce a collodion which would readily produce any amount of intensity with iron only; but he thought it a most undesirable thing, as it destroyed the chief end and advantage of iron development.

Mr. HILL asked if Mr. Vernon Heath did not propose a method of developing with pyrogallic acid based on a similar principle. It was somewhat singular that before knowing anything of the subject of Mr. Simpson's paper he, Mr. Hill, had remarked to Mr. Simpson that he thought an excellent plan of obtaining softness would consist in developing without free silver.

Mr. SIMPSON remarked that when Mr. Heath developed with pyrogallic acid, he adopted the principle of diluting the developer as much as possible so as to secure detail first, and intensity after. He now used an iron developer, but it was based on the same principle, and with even superior results.

Mr. HUGHES remarked that the intensity of collodion depended mainly on the character of pyroxyline. He had recently had an opportunity of seeing some of the Parisian operators at work, and they rarely needed to intensify at all; iron alone was sufficient.

Mr. MATTHISON observed that a little, in his case, depended on the especial formula he used for his developing solution. It consisted of 10 grains of iron, 30 drops of acetic acid, and 3 drops of strong ammonia.

Mr. HUGHES remarked that probably acetate of iron would be formed.

Mr. MATTHISON said the same result did not follow if acetate of ammonia were added instead of the acid and ammonia separately.

A MEMBER asked the effect of citric acid in the iron developer.

The CHAIRMAN said it would make development slow if added in any quantity.

Mr. HUGHES said a very small quantity of citric acid was sufficient to retard development with iron very considerably. He had used a 60-grain solution of iron, with a little citric acid, and it required three minutes to bring out a properly exposed plate.

Mr. HILL remarked that nitric acid would have a similar effect.

Mr. HUGHES observed that the result would be very different. Nitric acid would impair density; citric acid did not do that, but it produced a blue colour, which was very deceiving.

The CHAIRMAN showed some very fine instantaneous stereoscopic pictures.

A conversation ensued on the merits of combinations of lenses and single lenses for instantaneous views, in which nothing was established.

Some specimens by the panoramic lens sent by Mr. Ross were shown by Mr. Hill. It was generally thought, that although straight lines were curved in the pictures, the amount of subject gave them great advantages as regards pictorial effect.

A bath and dish of ebonite were shown by Mr. Moens, and considered to have great advantages should the material turn out in all respects suitable for photographic purposes.

Mr. SIMPSON showed "The Lady of Shalott," and "Early Spring," by Mr. H. P. Robinson, both of which were much admired; the landscape being generally regarded as one of the finest results of the camera yet produced.

After the usual votes of thanks the proceedings terminated.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 30th October, 1861.

IT has been a constant source of surprise that amid the anxiety to obtain a really good dry collodion process—one combining certainty of results with quickness of action—that more consideration should not have been given to the suggestions and recommendations of the Abbé Despratz. He investigated the subject in a very rational manner, and published a lucid exposition both of the theory and the practice of dry collodion with the simple addition of common rosin. Probably the reason this modification of collodion has found so little favour lies in the fact of its extreme simplicity. Had the Abbé pompously put forth a complicated formula after the usual model of an apothecary's prescription or a fantastical cook's recipe, his dry collodion process would have made as great a noise in the photographic world as many of those which enjoyed an ephemeral popularity, but which are now consigned to oblivion. Fortunately the Abbé's suggestion can suffer no harm by the indifference exhibited towards it. After all the empirical formulæ have been tried and found wanting, its merits will be duly recognized and acknowledged.

It is just possible, that many who tried the Abbé's formula may have failed in success at the first essay, but had they shown the same perseverance and determination to succeed as exhibited by Mr. Van Loo, of Amsterdam, photographers in search of a practicable "dry process" would have adopted "rosin," and let the nostrums, so much vaunted past times, pass with the indifference they so much merited.

In connection with the subject of "Colour in its Relations to Photography," it must have struck every photographer, when viewing the photographic image received on the ground-glass, that the image appears to possess much more colour than the object itself. This phenomenon is due partly to the *concentration* or *condensation* effected by the reduction in size of the image of the object, and partly to an error in our sense of vision with regard to distance. In the image on the ground-glass, all the various distances of a landscape are represented on a plane surface, by which the eye is enabled to take them in unbiassed by the forms; neutral tints, which in nature are scarcely perceptible or regarded by the ordinary observer, become distinct as patches of colour in the image. In the stereoscope, especially, this phenomenon is strikingly apparent.

Again, when the eyes are brought into an abnormal position, as in looking between the legs, or under the arm, the landscape appears much more vivid in colour. In explanation of this well-known fact, it has been suggested that it is due to an augmented pressure upon the brain, or to the different accommodation of the eye for vertical and horizontal lines; but it is to be considered then, even when in an easy reclining posture, where this pressure on the brain cannot exist, the heightening of tints in the landscape is seen with great distinctness by viewing the inverted image of the scene through a rectangular prism, even if the head be held in its natural position.

The more rational solution of the phenomenon would appear to be intimately connected with our perception or non-perception of distance. In gazing at landscapes, the ordinary habit of most persons, artists excepted, leads them to pay attention to the forms and *distances*, (which alone have a practical value as objects of observation), and to neglect the *colour*, particularly those portions of it which are subdued. If by any means the mind is prevented from dwelling on distance, it is thrown back on the remaining element, colour; then the landscape appears like a mass of beautiful patches of colour, heaped upon each other, and situated more or less in a vertical plane.

A perpendicular position of the eyes reduces very considerably our perception of depth or distance, so that false estimates of it are formed by the eyes in this new situation. With the exception of objects in the foreground, all objects seem to lie not far removed from the same verticel plane.

In normal vision with a single eye, there is certainly, in a binocular sense, no perception of depth, nevertheless, the mind occupies itself with the idea of distance, and if the objects are familiar, there is no augmentation of colour perceived. By inverting the image of the landscape with a rectangular prism, the objects fall into almost one plane, are diminished in apparent magnitude, and the mind, unable to trace distances through this maze, is forced to dwell on the mass of tints presented.

With the erecting or vertical telescope, in proportion as the objects are divested of the idea of solidity or depth, can their more delicate tints be preserved. Objects, which in normal vision seem to us nearly without colour, are best fitted for these observations; a bare pile of stones and dry mud viewed through a telescope, appears often like a richly tinted water-colour drawing.

It would seem probable that if we could add to paintings of landscapes the element of distance, the mind occupied with this would no longer dwell on the richness of the tints. This is confirmed by coloured stereographs of landscapes, which out of the stereoscope seem exaggerated in tint, when placed in the instrument no longer appear too highly coloured.

From these considerations it would appear, that when the mind is engaged with the perception of distance, the *presence* of colour is often overlooked; its *absence* may remain unnoticed from the same cause, for in uncoloured stereographs of objects that are perfectly familiar to the observer, it will sometimes be noticed, that those articles which do not greatly differ in colour from the tint of the photographic paper, are seen in the stereoscope with an approximation to their natural hues; upon withdrawing the slide from the instrument no trace of such tint is perceptible. Objects that are free from lustre, as well-known carpets, answer for this purpose. That this should be the case with the tinted photographic representations of white objects can, of course, be explained in another way.

Speaking of the tannin process of Major Russell, Sig. L. Alivari the eminent Florentine photographic artist, writes to the editor of the *Le Moniteur de la Photographie* the following testimony in its favour:—"It is the only dry collodion process that possesses any merit, and which can replace the Taupenot process by its simplicity and rapidity. I have made several trials of it, against my inclination, for I am rather prejudiced against innovations, and I have obtained excellent results. I do not doubt that the same success will attend the experiments other operators may make with it."

PHOTOGRAPHIC EXCHANGE CLUB.

Dear Sir,—As secretary of the Photographic Exchange Club, I am desirous of relieving your correspondent R. M. from any fear that he, or any other member of the Club, will receive duplicate copies of any print forwarded for exchange, as I certainly consider it part of my duties to prevent such an occurrence, by a method of checking each arrival and dispatch, which has enabled me to make some 300 exchanges, with 20 or 30 different members of the late Stereoscopic Exchange Club, without any difficulty.

Of course, I know nothing of what exchanges have already taken place among the members of the late Stereoscopic Exchange Club, who may likewise belong to the present Club.

The one thing needful to success, is this, that gentlemen will not be content to be passive members of the Club; for example, if one or two energetic members send in their good prints by the half-dozen, from each negative, large and small, it is likely to give the referees some trouble to get rid of them, if the other members don't respond.

I am, dear sir, yours respectfully,

Frank Howard.

Stockwell, Oct. 26th, 1861.

SUNDAY PHOTOGRAPHY.

Sir,—As regards the Sunday question, notwithstanding the letter of "A Doorsman," I contend that it is not by compulsory closing of photographic studios on the Sunday that the "dens" will be got rid of, but by the abolition of "doorsmen" altogether; it is they that keep up the vicious system; it is their importunities that inveigle so many victims into such disreputable places; and we find that those disgraceful scenes, such as have been made the excuse for enveighing against Sunday photography, did not occur on Sunday, but in this, as on another occasion, where the "lady" photographer and her "doorsman" figured in the police report, it was in the ordinary week's business.

Now I contend, that as there are in all large towns (and even so in small ones) many who, from the close application they are forced to give to their business, have no possible time to have a portrait taken except on Sunday, and if such persons do not believe it to be religiously wrong, I maintain that they have a just right to do so; and no compulsory law to prohibit them will convince them to the contrary, but only serve to strengthen their conviction, that such interference is but intolerance which ought to be resisted. I am, sir, your obedient servant,

J. Walter.

Lyme Regis, Oct. 19th, 1861.

Sir,—Although there have been several letters inserted in the pages of the News of late respecting Sunday photography, still I hope you will allow me to give my opinion as to a method of suppressing the Sunday trade in photography,

I think it would tend to abate the nuisance by obtaining the names of photographers who keep open their places of business on Sundays, and inserting their names and addresses in the columns of the News; and should the proposed "London Photographic Sunday closing Association" ever be permanently established, that they should publish the list in the advertising columns of some daily newspaper having a good circulation in every town in England, Scotland, Ireland, and Wales, so that the public may at once see an entire list of all the photographic Sabbath breakers.

Unfortunately, I am one who is shut up amongst the poisonous chemicals on Sundays, and were I to demur against such, I should very soon be informed that I must look out for a situation elsewhere.

I, for one, will gladly give my portion towards a fund for the open exposure, by advertisement, of the keepers of these vile dens, although, I am sorry to say, there are many photographers of high-standing who persist in keeping open on Sundays, as they say, to oblige parties who are closely engaged at work in the week-days.

Why then, ought not the photographer's operator enjoy the Sabbath as well as the mechanic or other tradesmen? Perhaps some of the vile Sunday-photographers will answer this question.

Not wishing to encroach upon the pages of the NEWS, I will conclude by subscribing myself, A SUNDAY OPERATOR.

TAXES FOR PHOTOGRAPHY.

SIR,—As a subscriber to the NEWS from the first day it appeared, allow me to ask, if you are aware of the injury you will probably do to photography by publishing such restrictive propositions as have appeared lately therein.

Photography is, and should always remain, as free as the light which is its life. No Royal Commissioners have injured it to the thousandth part of the extent that some of your correspondents would; and what can the Royal Commissioners think of a fine art which trembles before the success of the parties denounced? Sir Charles Eastlake might as justly attempt to stop the poor unfortunate ones who wander from town to town, silhouetting and painting extraordinary representations of the human figure; or Fenton, and Bedford, Silvey, and others of the same class, might with as much reason protest against any one photographing who was not as proficient as themselves.

Pray do not allow the patient to be poisoned, that you may show your skill is recovering him; and oblige every true lover of photography, as well as your correspondent, LUX.

Talk in the Studio.

THE PHOTOGRAPHIC EXCHANGE CLUB.—We have pleasure in informing our readers that a good number of names of gentlemen anxious to join the Photographic Exchange Club have already been forwarded to the secretary. As, however, several have not yet sent pictures, the distribution of Exchanges will not take place until early in December. It is desirable, that the prints for that exchange be forwarded to the secretary as early as possible.

PHOTOGRAPHS OF GHOSTS.—The *London Review*, in an article on the tendency in modern literature to the revival of ghost stories, suggests to the writers as a means of verification, that they obtain photographs of their spectral visitors. It says: "Now, if the spectre can ask the favour, let science do it a good turn Let optics and chemistry catch this modern ghost and photograph it! It can fix the tails of comets and the atmosphere of the sun; the other day a photographer at Berlin caught a stream of electric light flowing out of the bronze spear of Kiss's "Amazon." A ghost can hardly be less material, if it wear crinoline, is helped twice to beef, drinks claret, and wants a portrait taken. The photographer's plate is liable to no delusions, has no brains to be diseased, and is exact in its testimony. We will believe even in the modern ghost if it can be fixed on paper. And it can surely walk into Claudet's or Mayall's, if it can go to the theatre.

CHINESE PHOTOGRAPHS.—We understand that Signor Beati, so long engaged in China and the East in photographic operations, has just arrived in this country with a large stock of pictures, many of which, we understand, include scenes during the late war.

To Correspondents.

J. H. M. RITSON.—Prints may be kept a few days in a sensitive case, without much deterioration, but they will not tone so readily as if done at once after printing.

H. S. S.—The stains caused by iron developer may be removed by oxalic acid, or "salts of lemon." 2. We do not prefer the use of citric acid with an iron developer; but you may use 1 grain of citric acid in place of 15 minims of glacial acetic acid.

THOS. WARDELL.—The principle of the bath tester to which you refer—that of the hydrometer—is good. We cannot, of course, speak of the accuracy with which they are manufactured. 2. Oxide of silver for correcting the nitrate bath may be had of almost any chemist, or may be very easily prepared impromptu.

J. L.—Dallmeyer's No. 2 B lenses, to which you refer, are larger, and cover more than is necessary in stereoscopic pictures. If you require lenses to serve for stereoscopic and card pictures, the No. I B lenses of the same maker will answer your purpose.

G. DE SANQUI.—We are obliged by the extract, which shall appear.

B. Z., LONGTON.—We will take an early opportunity of trying the solution. Bichloride of mercury is the basis, we perceive, as in most of these preparations.

M. U. D.—In working the solar camera the paper is much more sensitive if used wet. Mr. Smith's address is, George Street, Euston Road.

DEVON.—The amount of washing you give your plates, both before and after the albumen, is insufficient; and when there is free silver present, any hesitation in the flowing of the subsequent preparations very easily causes marks. Wash more thoroughly, especially before applying the albumen solution. The gallic acid solution may be used in a dipping bath, and may be used so for a dozen plates without injury.

FREDERICK BARTON.—We are obliged by the specimens and interesting communications which arrived in due course, the acknowledgment simply stood over for lack of space. The prints are very fine as reproductions, and the printing excellent.

G. HILMAN.—Place the oxide of silver in a bottle with a little distilled water; shake up well, and add a few drops of the turbid solution to the old silver bath. Agitate well, and when it is quite neutral, or slightly alkaline, expose to light for some hours. Now filter the solution, and strengthen with a little fresh silver if it be weak. Try a picture, and if the shadows are not quite clean, add a trace of nitric acid.

N.—The prints 1 and 3 appear to prove your position as regards weak baths; but we should like to know more of the conditions. The stains appear to have been caused by contact of the finished print with some acid. Measles, or the defect to which that designation has been given, is a very definite thing, and when once seen does not admit of any mistake. It consists in a number of yellowish brown spots mottling the print all over. It always arises from imperfect fixation, the dark spots being caused by decomposed hyposulphite of silver. We have seen similar stains to those in your prints from contact before the print was perfectly washed from the hypo with citric acid, and other acids will produce a similar result. In order to judge correctly as to the qualities of the lens, it would be desirable to know its focal length.

THE SPOON PLATE HOLDER.—We have received from J. H. J. a letter complaining that having sent stamps to Mr. Rendle, of Ilfracombe, and receiving no acknowledgment for several weeks, and then only a letter say that the delay was caused by the difficulty of procuring, in a country place, the india-rubber required. We have received a letter also from M. A., giving a similar explanation of the delay, and initmating that the article would probably be undertaken by some London manufacturer, of which due notice will be given.

M. A.—We received your former letter. The answer was delayed, partly by pressure upon our space, and partly from a wish to know more of the plate-holder before answering. We have seen the one sent up to London. So far as we can judge, the cost of making them, so as to be convenient and efficient, would be much more than 1s. 2.—There is no infallible sign to guide the inexperienced eye as to when a print is properly fixed. It sometimes happens that when a print is partially fixed, opaque spots are seen on holding up the picture to the light, which indicates that the silver is not entirely removed from those parts. It is the safest plan for those whose experience is not a safe guide, always to use a fresh 20-per cent. solution of hypo. If the paper be thin *Saxe*, 10 minutes will be sufficient time for fixing; if thick *Saxe* or thin *Rive*, 15 minutes will be sufficient; if thick Rive, 20 minutes may be required. Where that length of immersion renders the prints too light, they have not been printed sufficiently deeply to begin with. Where the delicate clouds of which you speak are present in the negative, but disappear in fixing, the print must be either printed deeper altogether, or the sky alone may be printed deeper. In the print you sent, the whole picture would have borne deeper printing. 3.—We shall be glad to receive a description of your print washing apparatus. There is no test sufficiently certain and delicate to decide when a print is freed from all traces of hypo. A solution of nitrate of silver is discoloured at once by any sensible quantity of hypo. A solution of protonitrate of mercury is still more sensitive to its presence. But neither of these are considered quite certain tests as to the perfect washing of prints. Any deviation from the prescribed plan of long washing and repeated changes of water, requires careful experiment, guided by an experienced judgment.

A STEREO AMATEUR.—The lenses used by Mr. Fry, for his instantaneous views, are Dallmeyer's rapid stereo lenses. The No. 1 B of the same maker would be slightly more rapid still, and would undoubtedly, with good light and chemicals, in proper condition, give instantaneous results for stereoscopic pictures.

J. B. B.—*Rive* paper will give you the most delicate detail and the greatest brilliancy.

J. C. H.—We are glad to learn that the lens we recommended proves so satisfactory Dextrine may be used for mounting prints. 2. A new solution of hypo, 20 per cent., that is 4 ounces in a pint of water, is strong enough for fixing prints; if it fail to do so it must arise from having been used for too many prints, so as to become exhausted.

J. P. E.—We are obliged by your communication.

A PHOTOGRAPHER.—The only practicable mode of taking photographs by night, that we know of, is by the *photogen*. Gas light would not be sufficiently actinic. 2. The preparation of the "liquid chromatones" is known, we presume, only to the manufacturers. We think their use is a mistake. The difference in tones in paper prints is due partly to the quality of the paper, partly to the kind of toning solution, and partly to the length of time the print is kept in the solution. The darker tones are obtained by a long immersion.

C. K.—Your toning solution has probably been acid, and the traces left in the prints have decomposed the hyposulphite. Possibly you have not washed the prints thoroughly before toning. The chloride of gold should be neutral, and the proportion of acetate of soda is 30 grains to 1 of gold.

H. C. H., N. X., A SEARCHER, C. U., W. C., HENRY ROSE, C. DE LANGUE, AN ARTIST, . C. V., D. H. F., and several others in our next.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 166.—November 8, 1861.

PHOTOGRAPHY AND THE EXHIBITION.

Those of our readers who remember how large a share of the attention of the last meeting of the Photographic Society was engrossed by the prospective position of photography in the forthcoming International Exhibition, and how important are the issues which have arisen since, will naturally expect to find, in our report of the first meeting of the winter session, some allusion to the matter: possibly they will look for some expression of regret for past miscarriages, probably for some intimation that the hope held out in the last number of the Society's *Journal*, of renewed effort on the part of the Council had ripened into action.

Singular as the fact may be, however, not a word of any kind was uttered on the subject, either by officer or member. Notwithstanding that the topic has occupied a large share of the Society's *Journal* for months past, in the meeting it was entirely tabooed. The Chief Baron has made it a custom for some years, in opening the winter session, to pass in brief review the events of interest to the Society which have transpired since it had last met. On this occasion we naturally looked for some allusion, characterised by the good sense which usually distinguishes the worthy president's remarks, to a subject of such vital interest. For the first time, however, if we are not mistaken, on such an occasion, no introductory remarks were delivered from the chair. No question on the subject was asked by any member: the Exhibition was entirely ignored. So far, therefore, as there is any official intimation, the Society does not appear to have taken any further action, but may be regarded as having practically ceased to interest itself in the matter.

If the Society be considered as representing photographers at large, Her Majesty's Commissioners must be struck with their extraordinary supineness in the matter. Whilst other branches of art and industry are represented by the various trade committees, and local committees, photography alone is unrepresented. True, as we announced in our last, a committee will be appointed, and we trust an efficient one; but we should have been better pleased, if it had been the result of more consentaneous or representative action amongst the photographic community at large.

We are glad, however, to believe that so far as the question of contribution is concerned, the best of our photographers will not be inactive. We are glad that the recommendation, to abstain from contributing unless the demands of the Society were complied with, which at one time formed part of the Society's plan of protest, was quietly allowed to drop, and that whatever might have been the views of the Council in their corporate capacity, those of them whose contributions will add grace and importance to the Exhibition, have duly applied for space in the proper department.

We are especially glad that the idea which at one time seemed to find a few supporters, of getting up a "little go" in opposition, seems to be entirely abandoned, and that photography is spared the stigma of the pitiful failure which must have resulted. And we congratulate the South London Society, for having at least contributed its share towards assuring Her Majesty's Commissioners that photographers are not entirely indifferent to the representation of their art in the grand gathering of the world's art and industry. How far their memorial influenced Her Majesty's Commissioners we have no means of knowing; but we may set down the two facts in juxtaposition, that they memorialized the Commissioners, and that within a week or two afterwards we were authorized to announce that a committee would be appointed.

Apropos of this subject we may notice that a contemporary commenting on this act of the South London Society, and rating it in "good set terms" for its presumption, seems to have some queer misapprehension of the law or facts of the case. "It was altogether an irregular, not to say an illegal, proceeding," on the part of the Society to adopt such a memorial without previous notice, it is stated; and it is added that the memorial could not be the document of the Society, because each member did not give his individual assent to it. We are almost tempted to believe that our good friend, the editor of the *British Journal*, is indulging in a little badinage at the expense of this "small (not to say very small) suburban society." The notion is really as new to us as we apprehend it is to all our readers, that a motion may not be put and adopted by a meeting without previous notice; and that a resolution passed *nem. con.* by a meeting of a society, regularly convened, and fairly attended, is not the document of that society. We have been in the habit of attending many meetings of all kinds for the last score of years, and until now we never heard such an idea mooted; but we have, on the contrary, frequently known most important motions, absolutely have their origin in meetings, growing out of the immediate proceedings, and without any premeditation whatever, passed by small majorities, without anybody dreaming of disputing their legality. True, all motions having for their object the alteration of the rules, or the modification of the constitution of a society, require that previous notice be given, and that simply because such notions involve not merely doing some new thing, but also setting aside something formerly agreed to. We can assure our contemporary that it *is* customary to pass motions without previous notice, and that societies *are* in the habit of adopting, as their collective act, resolutions agreed to even by a majority, not to say unanimously. Nay, more, that the answers returned a few months ago to the appeal of the parent society were chiefly the results of motions put without notice, and adopted as the acts of the several societies, without any attempt to consult them individually. In fact, we believe no rule is more universal, or better understood, than that the decision of a majority in any meeting properly convened, is the recognised act of that meeting, provided it does not contravene any rule or decision already in existence, in which case, as we have said, notice should be given. Any dissentient individual may record his protest, for self-protection, but so far as the legality and representative character of such decisions are concerned, is not matter for doubt.

We incline to the opinion, however, that our contemporary was what is vulgarly termed "chaffing" the South London Society. We cannot believe that a serious taunt, as to its "smallness" would be levelled against a society of three or four score gentlemen for doing promptly what they conceived necessary to be done. Any notion of an actual sneer would be too suggestive of some feeling in connection with the recent severance of representative and journalistic ties, a feeling of which we would not willingly believe our contemporary to be capable.

ON THE NATURE OF THE PHOTOGRAPHIC IMAGE FORMED IN PRINTING AND TONING.

BY T. A. MALONE.*

After an apology for the extemporaneous character of his remarks, and some observations on the interest and im-

* An extemporaneous address, delivered at the meeting of the Photographic Society, on the evening of Tuesday, November 5th, 1861.

portance, as well as the difficulty, of the subject, Mr. Malone proceeded to ask :

What was the photographic image, in what manner did it act, and in what manner was it acted upon by the various agents employed in its production and toning ?

As was well known, considerable difference of opinion prevailed on this subject: some held that organic matter, the paper, served merely as a vehicle to support the chloride of silver, on which the image was formed; others held that it served as an adjunct in producing the image. There was no doubt, however, about chloride of silver being the basis, and the question then presented itself: How does light act on the chloride of silver? The question had been answered in various ways. Quite recently, the eminent Dutch chemist, Mulder, had given considerable attention to the subject, having thought it desirable to conduct some assays by the wet method, precipitating the silver as a chloride. Finding, of course, that chloride of silver was liable to be darkened by light, he wished to know accurately what was the action of light upon it. Fresenius, the celebrated analyst said that chloride of silver exposed to light, lost weight. This loss of weight was due to the liberation of chlorine. Light acting upon chloride of silver did liberate chlorine; that was ascertained: there was no question on that subject. Now came the difficulty, however, and the question was: Did the light reduce the whole of the silver, and liberate the whole of the chlorine? Some held that it did; that was, as far as the light could go. Others held that it only liberated a portion, and formed a subchloride of silver. This statement of the case, at first sight so simple and easy, became very difficult of proof, because of the nature of the process. In carrying out the process, the whole of the chloride of silver was never exposed to light, and it would be evident at once how a difficulty thus arose. They knew light darkened this substance (placed in water in a bottle), but it darkened it on the surface; and that darkened surface at once acted as a screen to all the rest. Now, what was true of a bottlefull, some said, was true of each molecule; the surface of each particle was acted on and blackened by light, but the interior was shielded by the darkened surface, and so the action was not complete. If this darkened substance were treated with fixing agents, such as hyposulphite of soda, &c., they found it was separated into a solution containing chloride of silver and spangles, resembling metallic silver. This was the whole account of the transaction, said some. But these spangles bore no resemblance to the dark substance, and the proportion was so small, that it did not appear credible they could possess so much colouring power. This view involved that metallic silver had not that colouring power. He was, however, prepared to show that it was quite possible that it was metallic silver entirely, and not a subchloride, an oxychloride, &c. &c., as had been supposed.

In order to arrive at these conclusions he proposed to abandon analysis, which had presented so many difficulties, entirely, and proceed to the enquiry purely by synthesis. That was, he would produce by chemical means a similar substance, and show that it was metallic silver. This being done, he thought they would be in a fair way to clear up the difficulty; and analysis having failed through their not being able satisfactorily to isolate the substance, he thought it would be admitted that the synthetical method was quite a legitimate resource. He had been led to this method of examining the matter, by Professor Faraday's paper On Ruby Gold, in the transactions of the Royal Society, the perusal of which, led him to think that analysis having failed, synthesis might solve the problem. The method Mr. Faraday had adopted in regard to ruby gold, he proposed to follow with regard to reduced silver. Mr. Faraday had simply shown that there was good reason why the ruby tint, produced under some circumstances by gold, and which by some was believed to be the result of some chemical combination, was simply metallic gold, in a very fine state of sub-division. Chemistry would of course demand more than this, it would require the atomic constitution and weight. A certain bulk of this ruby gold must be taken and weighed, produce it as yellow gold, and then weigh again, and show that it has not lost one particle of weight. This, Faraday thought he had done; but not with all the precision analytical chemistry demanded. Well then he, Mr. Malone, thought they might also have ruby silver. Of gold there were various tints produced, they had ruby gold and blue gold, and he believed the same colours might be had in silver. And if this were the case, and they had thus the two opposite ends of the spectrum, and—he might add he believed yellow—why not all other variations or combinations of colour? If he could show to them this characteristic of gold, and show the analogy in this respect between silver and gold—and, he might perhaps add, platinum also—he thought they could come to no other conclusion, than the experiments of Faraday tended very materially to explain the nature and formation of the photographic image. This was not a new statement: as many present were aware, he had already expressed his conviction that there was no reason whatever why the photographic image might not consist entirely of metallic silver entangled with organic matter. He would now proceed to illustrate his position.

Gold, as every one knew, was soluble in nitro-muriatic acid. For the purpose of this experiment he had dissolved some pure gold in aqua-regia, and evaporated to dryness, which he now produced. They would notice that the red colour showed that all the acid was expelled. This chloride of gold he now dissolved in water. It might be reduced in a variety of ways: oxalic acid with the aid of heat would reduce it; it would fall in thin flakes of pure gold. Protosulphate of iron would reduce it, not in a ruby condition, but in a brownish or purple powder. Chloride of tin would reduce it in a rich purple powder, known as the purple of Cassius. It was long thought that this consisted of a compound of gold and tin, but it has since been shown that it consisted of pure gold in a fine state of subdivision. It would seem, then, that the colour of a reduced metal was largely governed by the agent employed in the reduction. The agent photographers had to deal with was light.

For the purpose of his experiments in obtaining the ruby gold, he might reduce it either by means of phosphorus, dissolved in bisulphide of carbon, or in ether. Those present interested in the electrotype process might remember the elegant method of reducing silver by means of phosphorus. When it was desired to electroplate a plant it was dipped into a solution of phosphorus in ether, and then into a solution of nitrate of silver, the phosphorus reducing the silver and giving the plant a metallic coating which served as a conductor in electrotyping. As phosphorus in ether would be less offensive in smell than bisulphide of carbon, he would use it for his experiment, but he had both present.

Mr. Malone now dissolved a piece of phosphorus in a little ether, remarking that it would be seen that there was no metallic base present, and no organic matter such as might effect the question, simply phosphorus, carbon, hydrogen, and oxygen. He would now add this to the solution of chloride of gold. This was done, and immediately a stratum of dark ruby colour was seen at the point of contact, which gradually increased until the whole became of the same dark tint. This was diluted with a large bulk of water without in any material degree attenuating the colour.

This colour, he remarked, was simply due to particles of gold in a very fine state of division, and although gold was the heaviest of metals, it would remain thus for years without settling. He called attention to the very great colouring power it possessed, notwithstanding the amount of dilution. The particles were so fine that they could not be all filtered out, but much passed through the finest filter, and this fact gave rise to the notion, in the first instance, that it must be in solution, not merely in suspension.

It did, however, eventually precipitate, and, by agitation in narrow tubes, it was found to settle, and could be collected as a deposit; and he (Mr. Malone) hoped shortly to be able to settle its atomic constitution. Having done that for gold, he hoped to do it for variously coloured silver, and that would not leave a shadow of doubt on the subject.

He would now perform a similar experiment with silver.

He would take a solution of the nitrate, because, as they were aware, the chloride was not soluble. [The lecturer then added a portion of the solution of phosphorus in ether to a solution of nitrate of silver, which immediately darkened in the same manner as the gold had done, and when considerably diluted with water, showed similar high colouring power.]

This high colouring power, he remarked, was, as in the case of the gold, solely due to the minute division of the metallic silver, as there could not be a doubt of the absence of organic matter, as usually understood. He was aware that Mr. Hardwich held that organic matter was necessary to the production of the red tint in silver, and that he stated that gelatine, saturated with nitrate of silver, exposed, and dissolved by the aid of potash, presented a blood-red colour. He believed this colour was simply due to the state of division in the metallic particles, and he conceived that he had a perfect right to assert that it was simply ruby silver—finely divided silver. It was pure assumption to say that it was the result of any combination with the gelatine. Other organic substances might aid in producing this fine division of particles; but he believed the colour was in all cases due to such division.

At this stage of the experiments, Mr. Malone filled a bottle with oxygen, and then placing in it a piece of phosphorus, which he ignited, procuring an exceedingly brilliant white light, for the purpose of better showing the ruby colour of the solutions.

He now referred to the question of toning. On adding to a solution of ruby gold, or ruby silver, a little hyposulphite of soda, it became purple. It was generally supposed that this was due to the action of sulphur. He thought that there was room to doubt this. Chloride of sodium, common salt, would produce just a similar effect. This showed that sulphur was not necessary to the production of the result. Chlorine alone would do it. Mr. Hardwich was aware of this, and attributed it to the formation of a sub-chloride of silver. This could not be true, however, of gold, as the yellow colour would detect it. As regarded the rationale of the matter, they all knew that different degrees of subdivision of bodies gave different colours; the point was to find the process. In regard to gold and silver, he thought he had found it. Gold leaf when beaten very thin, became green; and the same leaf might be in part ruby by transmitted light. Other tints might also be produced.

The lecturer now added a little of a solution of hyposulphite of soda, to the solution of ruby gold, which assumed first a purple tint, and then a decided inky hue.

A little of the ruby gold solution spilled on paper, he observed, became of a purple tint, probably from some chloride in the paper, or possibly the alum might cause it. The principle here involved, he believed, was that on which toning was effected, and it was probable that the varieties of toning were due to one simple difference, the acceleration or retarding of this deposit. Photographers were aware under some circumstances the prints which had appeared sufficiently toned, lost their colour again in the hyposulphite of soda. He thought it very probable that this circumstance would be easily explained on the principle to which he was referring.

The same principle which applied to gold would apply to silver. And if they could get the colours he had named, they could, by mixture, obtain any tint. These finely divided metallic particles would in fact constitute pigments. The speaker then referred to the experiments of Becquerel in securing the various colours of the spectrum on chloride of silver, each ray giving its own colour, whilst white light produced white, and stated that he had recently been making some experiments in the same direction. He had obtained copies of some roughly coloured French pictures, as also had M. Niepce de St. Victor, in which there was a decided approximation to the colours of the originals, the whites were represented by white, and the blacks by a dark colour. If the various colours of the spectrum could be produced by the action of light on chloride of silver, he thought there was a striking analogy between the experiments of M. Becquerel and those he was now pursuing. He thought he had proved that a very minute portion of metal indeed was sufficient to produce very intense colouring powers. He had before demonstrated that the eight-thousandth part of a grain of iodine was sufficient to give the colour to a silver plate, necessary for producing the Daguerreotype. They all knew that silver in some forms was black: sugar of milk, ammonia, caustic potash, and some other substances would throw it down from the nitrate on to glass, and when so thrown down, it was purple by transmitted light, as Liebig and Stas had demonstrated, and as was evident in the specimen before them. He thought then that the experiments he had brought before the meeting, and the facts he had stated, were calculated to throw considerable light on the subject of the formation and toning of the photographic image, and tended to show that finely divided metallic particles were quite sufficient to give the depth of colour without the aid of organic matter.

PHOTOGRAPHIC CHEMICALS:

Their Manufacture, Adulterations, and Analysis.

Phosphorus *and its compounds.*—The compounds of this element have not hitherto been used to any great extent in photography, although from the little that is known of their value in the art, there is no doubt that these bodies would well repay attention. Amongst them we find very powerful reducing agents, and the silver compound of one of the phosphorus acids possesses very valuable properties which have been utilized successfully by Mr. Maxwell Lyte. The element itself appears to possess a certain degree of photographic sensitiveness, inasmuch, as one, if not more, of its allotropic modifications is produced by the action of light upon the ordinary variety of phosphorus.

The element phosphorus is prepared by a somewhat difficult process: by the action of carbon upon phosphoric acid at a white heat the oxygen of the acid unites with the carbon, and sets the phosphorus free. As usually met with in commerce this element is a colourless, or faintly yellow, waxy-looking body, brittle in the cold, but of the consistency of wax at the ordinary temperature. It melts at a slight elevation of temperature (108° Fah.) and volatilizes readily at high, and in small quantities even at ordinary temperatures. The most characteristic property of phosphorus is its extraordinary inflammability, which is made use of to an enormous extent in the manufacture of lucifer matches. The statistics of this branch of manufacture are such as to appear fabulous. In England, where the manufacture is comparatively small, upwards of 6 tons of phophorus are used yearly, producing upwards of 50 millions per day. One manufacturing firm, Messrs. Dixon, turn out every year 2,160,000,000 matches, or more than sufficient to go round the earth if laid end to end. In Austria, the greatest seat of match making, two firms, those of M. Pollak, and M. Fürth, consume about 20 tons of phosphorus yearly, and as one ton is sufficient to tip upwards of 1,000,000 of their matches, these two makers alone produce the amazing number of 44,800,000,000 matches yearly. The total produce in Austria is estimated at 2,500 tons.

Mention has been made above of an *allotropic* modification of phosphorus: this term is used to express a condition which an element sometimes assumes in which it has different properties physically (and sometimes even chemically), from the same body in its ordinary state. Thus, the diamond is said to be an allotropic modification of carbon. In like manner, phosphorus exists in more than one allotropic state. The most important of these is the one which it assumes when the ordinary variety is kept heated in a close vessel under pressure, at a temperature of 450° Fah. After about three or four weeks, a quantity of about 2 cwt. may be completely converted into a hard brick-red substance, which, when properly purified, is known as Schrötter's Red Phosphorus. There is quite as much difference between the white and the red phosphorus as there is between two distinct elements, silver and copper for instance; and were it not that we can artificially convert one variety into another, they would be looked upon as separate elements. Their difference is strikingly shown by a comparison of their properties. The ordinary white variety of phosphorus is poisonous; evolves a strong odour; is phosphorescent; luminous in the dark; melts at 108° Fah.; is very transparent; almost colourless; freely soluble in various liquids; distinctly crystalline; so soft as to be easily indented by the nail; and at the ordinary temperature is as flexible as copper or lead. The red phosphorus, on the other hand, is innocuous when taken internally; nearly odourless; not phosphorescent; perfectly non-luminous; melts at above 500° Fah.; is opaque; varies in colour from nearly black with metallic lustre, to iron-grey, brick-red, crimson, and scarlet; is nearly insoluble in all liquids; is destitute of all crystalline structure, (amorphous;) is as hard as a common red brick, and as brittle as glass. The most important and conspicuous fact connected with the red phosphorus is, that it may be exposed to the air in the dry state, and freely handled with no fear of its inflaming; whilst the white variety is rapidly ignited in contact with atmospheric oxygen. This red variety is now much used in the manufacture of safety matches.

The most important compounds of phosphorus with which the photographer is likely to come in contact, are its oxides: owing to the powerful reducing nature of the lower oxides, it is not unlikely that they may be eventually used in photography. We shall, therefore, briefly describe them, as well as the principal oxide—phosphoric acid, which is already somewhat employed.

Hypophosphorous acid, a combination of equal equivalents of phosphorus and oxygen is now prepared in some quantities in combination with iron and other metals for medicinal purposes. It is made by boiling phosphorus and baryta water together till the vapour no longer has a garlic odour; the baryta is then to be exactly precipitated from the filtrate by cautious addition of sulphuric acid; the liquid, again filtered, may be concentrated by evaporation. Hypophosphorous acid forms a colourless, uncrystallizable, very acid solution, which has remarkable reducing properties upon silver and gold salts. From nitrate of silver the acid or any of its soluble salts throw down a white precipitate which soon turns brown, and is converted into metallic silver, the change being further accelerated by the action of heat or light. It is probable that a solution of hypophosphite of soda would prove a good developing agent for collodion plates, especially if there were no excess of free nitrate of silver present. The great aim of photographers at present should be to discover some more powerful developing agent, whereby the latent image—which by many high authorities is supposed to be impressed on the sensitive surface the moment light falls upon it—may be brought out. Certainly, to have a really instantaneous process a very sensitive and impressionable film must be used; but it is no less necessary to employ a powerful reducing agent. More, indeed, now depends upon the latter than upon the former, and we think from experiments tried in our laboratory that these lower acids of phosphorus will prove valuable adjuncts to the hitherto employed developing agents. They are not now suggested for the first time, but we do not think they have ever been used in practice beyond an experimental trial or two.

Phosphorous Acid.—Another reducing agent of this class, and one which is somewhat more manageable than the one first mentioned is phosphorous acid. A very good way of preparing it on the large scale is to pass chlorine through water on to some phosphorus at the bottom. The chlorine and phosphorus unite, forming terchloride of phosphorus, and this is immediately decomposed by the water with formation of hydrochloric acid and phosphorous acid. Care must be taken to keep the phosphorus in considerable excess, otherwise pentachloride is formed, which decomposes into the pentoxide, phosphoric acid.

The solution which contains, along with the phosphorus, hydrochloric acid, is to be concentrated in a retort, when the latter acid goes off and leaves the former in pure aqueous solution. Thus formed, phosphorous acid is a colourless, very acid liquid which must be preserved in close vessels, otherwise it has a tendency to oxidize and form phosphoric acid. It unites with bases, and forms phosphites. When a soluble phosphite, or the free acid is added to a solution of nitrate of silver or chloride of gold, metallic silver or gold is thrown down, the former being brown-black when precipitated from a cold solution, and black when precipitated at a boiling temperature. When the acid is concentrated at a gentle heat to a thin syrup it forms crystals; but when concentrated to a greater extent, like the hypophosphorous acid last mentioned, it decomposes water, evolving phosphuretted hydrogen, and becoming oxidized to phosphoric acid, the highest oxide which phosphorus forms, and by far the most important of its compounds.

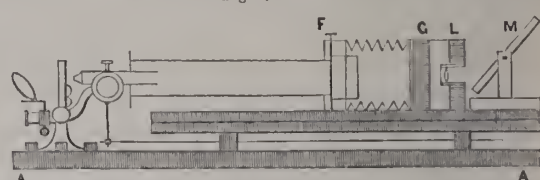
ON THE PRACTICAL APPLICATION OF PHOTOGRAPHY TO THE MICROSCOPE.

BY PROFESSOR O. N. ROOD.*

While the value of the photographic delineation of microscopic objects, as a means of accurately recording observations, seems to be generally acknowledged, yet, owing to the real or imaginary difficulties with which the process is beset, but very few working microscopists have adopted it. After eight months of steady experimental work on the subject, this fact appears to me a matter of astonishment, for the difficulties which are not inherent mostly disappear when proper precautions are taken. I propose to mention briefly certain points in my experience, and to indicate the methods pursued.

Arrangement of the Apparatus.—The microscope is brought into a horizontal position, and connected with a camera box, by a blackened pasteboard tube: much vexation will be avoided by constructing at the outset the arrange-

Fig. 1.



ment seen in the woodcut. *Fig.* 1. Blocks are fitted around the foot of the microscopic that it may be held firmly in position, and the camera box slides between parallel strips of board, so that its distance from the microscope can be varied. The length of A A is seven feet. The frame holding the ground-glass slides is at G; behind it, at L, is a door on hinges, carrying an achromatic lens of two inches focal length, for the purpose of magnifying the image on the ground-glass while focussing: the glass plate should be finely ground. A tube lined with black velvet is to be inserted in the compound body, as recommended by Shadbolt, if the eye-piece is not employed. Precautions must of course be taken that light does not enter at unguarded points. At F is a rod connected with a flap of blackened sheet brass in the interior of the box, with which the exposure of the sensitive plate is very conveniently effected. It is obvious that while the operator is manipulating the mirror, or using the stage-movements, on account of the length of the apparatus, it is impossible for him to see the ground-glass, or even to know when light has been thrown on it, a plane mirror, mounted as seen at M, reflects the image of the ground-glass, enabling him not only to arrange the illumination with nicety, but to select the microscopic object, and to focus on it approximately. While the mirror is in use, the door carrying the achromatic lens stands open; the mirror is

* From *Silliman's Journal*.

afterwards removed, and the focal adjustment completed with the help of the lens, by the rod and lever attached to the rack-work of the microscope. If the rack-work is moderately good, this arrangement is very delicate. When a high magnifying power is employed, it is essential that the microscope be provided with stage-movements to bring the object into its proper position. The lever stage is not to be recommended for this purpose.

Illumination of the Object.—That direct sunlight is greatly to be preferred is admitted by those who have experimented on this point. With light from a white cloud I have obtained negatives, in from one to three minutes, with 1 inch and ½ inch objectives: though not highly magnified, they were inferior to those taken with sunlight. Shadbolt obtained negatives by concentrating the light of a small camphine lamp on the object with two lenses. Wenham in repeating this experiment, met with no success. I concentrated the light of two flames of "burning fluid"* lamp with a bull's-eye condenser on the object, employing the 1 inch objective without an eye-piece, and obtained, with several samples of collodion from the different manufacturers, absolutely no image at all, after an exposure of five minutes. With samples prepared by myself, tolerably intense negatives were obtained in four minutes. With the ½ inch objective a faint image was obtained in the same time. For my own work direct sunlight is always employed.

It is well known that the proper display of microscopic objects requires that great attention should be given to their illumination, not only in degree, but in kind: much has been written on this subject, and an astonishing amount of labour bestowed on it. All this applies with double force to the illumination preparatory to the introduction of the sensitive plate: refined methods here find a most useful application. If the power employed be under 100 diameters, the plane or concave mirror will answer, if the stage be provided with a diaphragm-plate having apertures of different size. The mirror should be most carefully adjusted, so that the maximum of distinctness in the image on the ground-glass is obtained. I was kindly furnished by Prof. Chas. A. Joy with a *silvered* mirror which Liebig presented to him some months ago, while on a visit in Europe. It furnished brighter light than the ordinary amalgam mirror: the use of Liebig's mirror for this purpose, as well as for ordinary microscopic work, is to be recommended. With powers from 100 to 2,000 diameters, a condenser of some form is needed. For powers from 100 to 400 diameters, an achromatic condenser, adjustable by rack-work, was used. Such a condenser must be provided with a series of diaphragms, having circular apertures differing in size, also with a set of central stops for annular oblique illumination.

Trial alone will settle which aperture gives the clearest image in any particular case. As the lenses of this condenser were not large, I constructed for powers of from 400 to 2,000 diameters a Wollaston doublet, with an angular aperture of 40°, the lenses being ·5 and ·6 of an inch in diameter. This condenser, when provided with a similar set of diaphragms, was found to answer very well, both as to the degree and quality of the light, negatives being obtained in 15 seconds enlarged 1,500 diameters. As the chromatic aberration was not corrected, it was found easy to illuminate the object either with white or bluish-white light, use of the red or yellow rays being of course carefully avoided.

The proper distance of the condenser from the object is a point of much importance, and is best ascertained by carefully repeated trials. To obtain really good results much nicety in arranging the illumination is required: this is a matter in which microscopists are well practised; but, to secure the best results possible *under the circumstances*, as in photographing test objects, the art and patience of the operator is taxed to the utmost, and several days are often consumed before a really satisfactory result is attained, even in the case of a single object.

Focal Adjustment, &c.—Trouble will be saved by selecting the exact object which is to be photographed by the microscope in an upright position; the instrument is then inclined and connected with the camera. After the compound body is thus placed, if the objective is provided with a "screw collar" for correction, this adjustment must be *carefully made.* Even when this point has received attention, it by no means follows that the chemical focus coincides with the visual, and the exact correction necessitated by this difference must be ascertained by trial. This can be effected by the use of the fine adjustment (see Shadbolt's paper). Contrary to some observers I have found it necessary, when using sunlight, with both high and low powers, with and without eye-pieces, to make this correction carefully. The use of the rod and the lever and achromatic lens has already been mentioned. After the corrected image has been thrown on the ground-glass it will remain nearly unaltered from thirty seconds to ten minutes, according to the power and mode of illumination employed.

(*To be continued.*)

* "Burning Fluid" is a mixture of alcohol and camphine, commonly used in lamps in the United States.—Ed.

A FEW WORDS ABOUT GLASS POSITIVES,

WITH DEVELOPERS OF VARIOUS STRENGTHS, HOT DEVELOPERS, ETC., FOR WINTER PHOTOGRAPHY.

In a recent communication on negatives by positive process I promised at some future time a few remarks on the subjects given above. The season of the year is fast approaching in which I think it possible that the few hints that I may now offer will not be unacceptable to at least some of your readers. My last article was exclusively devoted to negatives; but as there are many photographers I know who confine their practice to glass positives, having a dread of negatives, and a fear lest their customers should not return for their prints. For such persons, principally, this article is now written; therefore I shall commence with the collodion and bath. My remarks, however, on that head will be simply a repetition of what was before published in my article on "Negatives by Positive Process," and I have, therefore, to ask the kind indulgence of those of my readers who have perused the article before alluded to, while this repetition is being made. The collodion I use is a good bromo-iodized one, which is free from crape-like lines, waves, and other irregularities, which gives a rich creamy and even film. The bath is composed of the purest recrystallized nitrate of silver, sold at 4s. 6d. oz., and not the ordinary crystallized at 4s., which, as far as my experience goes, is only suitable for printing, and which, if used in the bath, would be a never-ending source of fog and stains. My bath is composed as follows:—

Pure recrystallized nitrate of silver	40 grains
Distilled water	1 ounce.

In making an entirely new bath I generally dissolve 3 ounces of recrystallized silver in 33 ounces of distilled water. I then coat a large plate with collodion on both sides, and let it remain in the bath for a few hours, so as to saturate the solution with iodide of silver. At this season of the year a bath 45 grains of silver to the ounce of water would not be found any too strong. If everything is quite pure, a bath prepared as above will generally give very good results; but it sometimes happens that the bath may occasionally fog, to remedy which defect I keep in a separate bottle a dilute solution of nitric acid, as follows:—

Pure nitric acid	1 drop
Distilled water	1 ounce.

One drop of this dilute solution of nitric acid added to the bath will generally bring it into working order; but in no case do I add even this small portion of acid to the bath, if good results can be obtained without it; for it is a well admitted fact that if more acid is added to the nitrate bath than is absolutely necessary to the production of clean pictures, the sensitiveness of the film is considerably diminished.

The proportions of nitric and glacial acetic acid given in the formulas for developers, which are now about to be given, are so nicely balanced, that if more or less of either were used in proportion to the iron, it would be found to be injurious. Thus, if *less acetic acid* than is given were used, and the same quantity of nitric fogging would be the result: or *if less acetic acid and more nitric* were used, pictures of an unpleasant metallic glare would be the result; again, if *more* acetic acid, and the same quantity of nitric or less were used, pictures having a thickish deposit of silver more suitable for negatives than for positives would be the result. The developer I use in summer, which I will call No. 1, is made as follows:—

Protosulphate of iron	3 drachms
Glacial acetic acid	3 ,,
Nitric acid	3 drops
Filtered rain-water	20 ounces.

But in the winter season I keep five other developers in my dark room, as well as No. 1, which I label thus—1, 2, 3, 4, 5, 6, prepared as follows:—

No. 2.—	Protosulphate of iron ...	75 grains
	Glacial acetic acid	$1\frac{1}{4}$ drachms
	Nitric acid	5 drops
	Water	5 ounces.
No. 3.—	Protosulphate of iron ...	100 grains
	Glacial acetic acid	$1\frac{1}{2}$ drachms
	Nitric acid	6 drops
	Water	5 ounces.
No. 4.—	Protosulphate of iron ...	150 grains
	Glacial acetic acid	$2\frac{1}{2}$ drachms
	Nitric acid	8 drops
	Water	5 ounces.
No. 5.—	Protosulphate of iron ...	200 grains
	Glacial acetic acid	3 drachms
	Nitric acid	10 drops
	Water	5 ounces.
No. 6.—	Protosulphate of iron ...	250 grains
	Glacial acetic acid	$3\frac{1}{2}$ drachms
	Nitric acid	10 drops
	Water	5 ounces,

So that if any difficulty is experienced in getting pictures with a few seconds exposure with No. 1, we try No. 2 or 3 with the same exposure, and sometimes No. 6, and get satisfactory pictures in a dull light, which with developer No. 1 or 2 would be an impossibility. Photographers would find it much to their advantage in the cold and frosty weather if they would keep their vessels containing their bath and developing solutions in hot water during working hours, so that their temperature may be kept up to not less than 60 degrees, or even more than that, the difference this would be found to make in the time of exposure required we have found to be very great, somewhere about half the usual time being sufficient. I should think hot baths and developers would be found serviceable to those who are working instantaneous photography. Fix with cyanide as usual, and when dry, varnish with amber varnish.

T. S. Swatridge.

Princes Street, Yeovil, October 21st, 1861.

ON POSITIVE PRINTING.

BY EDWIN MUSGRAVE.*

Although I do not recommend that amateurs, whose printing is on a comparatively small scale, should albumenize their own paper, as they are more likely to obtain a good result by purchasing it ready prepared from a dealer on whom they can rely, than by preparing it themselves, I give here a formula for those who prefer albumenizing the paper themselves.

The first thing is the selection of the paper. I prefer the *Papier Rive* and Hollingworth's thin paper, as giving the best results in my hands.

The formula for the albumenizing solution is as follows: —To each ounce of albumen add ten grains of chloride of ammonium or sodium, dissolved in a quarter of an ounce of water. (Chloride of barium also gives a very fine tone. Some may prefer it. In that case it is requisite to double the quantity of the salt, to produce the same vigour of print as the other chlorides give.) Beat the whole up to a perfect froth with a bundle of quills or a fork. As the froth forms it is to be skimmed off into a flat dish to subside. When the froth has partially subsided, pour it into a tall narrow jar, or a bottle with a wide mouth, and allow it to stand for several hours.

An ordinary photographic dish is filled with the prepared albumen, by pouring it gently from the bottle into a glass funnel having a piece of clean muslin disposed as a filter, the beak of the funnel resting on the bottom of the dish to avoid the formation of bubbles. Having ascertained the right side of the paper, take a sheet by the two corners, bend it into a curved form, convexity downwards, and lay it upon the albumen, the centre part first touching the liquid, and the corners being lowered gradually.

"When the paper can be removed from the surface of the albumen without violently curling up, it is to be lifted by one corner, and allowed to drip for a few minutes, steadying it in a vertical position by holding also the adjoining corner with the other hand. After dripping for about a minute from one corner, the hand that steadied the neighbouring angle to that by which the paper was suspended is to be gently raised, so as to become in its turn the suspended corner, which proceeding will cause the albumen to flow off from a different corner to that from whence it first dripped, the flow being now at right angles to its former direction, After a few seconds—say half a minute—bring the corner next in succession to the highest point, and finally the the fourth corner upwards, taking care that each one comes uppermost in *regular succession*, so that the drip has flowed from each of the four corners. If the operation above described has been correctly performed, the paper will now be coated on the surface with an even film of albumen, scarcely flowing at all. The great point to be aimed at is to *keep it* in the condition it now presents—that is, an even, brilliant film; and to this end rapidity in drying mainly conduces.

"By attaching two American clips to a sheet of the paper the whole can be suspended in a vertical position from a cord. The paper should be hung with the *plain side* towards the fire, and as close to it as possible, so long as scorching is avoided. In about a couple of minutes the drying will be complete and the surface of the paper smooth and brilliant, provided that the manipulations have been correctly performed."*

The next operation is to sensitize the paper:—

Nitrate of silver	80 grains
Distilled water	1 ounce.

Lay the sheet of paper upon the solution in the same manner as described for the albumen: three minutes contact will be sufficient.

For those who prefer plain paper, Mr. Hardwich's citrate of soda salting-bath will be found to give a very fine warm tone with the alkaline gold toning-bath.

The salting solution is prepared as follows:—

Chloride of ammonium	200 grains
Citrate of soda	200 ,,
Gelatine	20 ,,
Water	20 ounces.

* Condensed from a paper read at a Meeting of the Edinburgh Photographic Society, and reported in the organ of the Society.

* Mr. Musgrave acknowledged himself indebted to the directions of Mr. Shadbolt in the *Photographic Journal* for the manipulations in albumenizing.

To prepare the citrate of soda, dissolve 112 grains of citric acid in the 20 ounces of water, and add 133 grains of the dried bicarbonate or sequi-carbonate of soda then add the remaining constituents.

Use Hollingworth's paper with the above formula, each each sheet being floated for one minute and then suspended to dry. Render sensitive by floating for two or three minutes upon the solution of nitrate of silver used for the albumenized paper.

Printing from the Negative.

The best kind of printing-frames to use are those with springs in preference to screws, as the latter are very apt to break the negative or glass of the pressure-frame. I prefer velvet myself as a pad behind the paper, as the short pile of the velvet presses the paper evenly all over, and secures fine definition.

If the negative be weak, with little intensity, print it in a very feeble light, with a thick green glass over it, by which means the shadows will be printed deep enough to give good contrast before the high lights are penetrated. But if the negative is intense, put it out in strong sunlight, so that the detail in the denser part of the negative may be printed before the shadows become too deep. You will by this means be able to get clouds if they are in a negative, supposing it to be a landscape—that printed in a diffused light would give only a white paper sky.

Occasionally one may have a negative that has been cracked; and, if the picture be of value, a print may be got from it by placing a piece of ground-glass about two inches above the pressure-frame, when the light carefully excluded from getting in at the sides, and place it in the sunlight to print. The result will be that you get rid of the objectionable white line caused by the reflection of the light from one side of the crack, and the print, if properly managed, will show scarcely any mark at all.

In some negatives the sky may be defective: in that case it is better not to paint out the sky of the negative, as doing so would prove the total destruction of the atmospheric effect. The best plan is to cover the sky with cotton wool, following the outline of the picture; and then, when the printing of the picture is completed, cover the part printed, take a piece of card, and shade the sky to the required tint, lighter at the horizon, increasing a little in depth towards the top.

When the print is removed from the pressure-frame it is placed in water, and the water is changed four or five times at intervals, till it is no longer milky. The print is then placed in a solution of salt and water, about a salt-spoonful of salt to a pint of water. This is to obviate the necessity of over-printing very much, and to prevent the toning and fixing baths reducing the intensity of the print. Allow the picture to remain in the salt and water from five to ten minutes: this will give a reddish tint to the print.

The print is to be steeped in fresh water, and is then ready for the toning bath.

Toning.

The toning-bath is prepared as follows:—

Solution of chloride of gold	1 fluid drachm
Carbonate of soda ...	... 10 grains
Distilled water ...	... 6 to 8 ounces,

The gold is best kept in solution one grain to the drachm of water.

The prints are to be immersed in this solution—if large, singly; small ones may be laid side by side, as many as the dish will hold, face downwards, and another set may be placed on the top, face upwards. Take care that the faces of the prints do not touch each other, or red spots will be the result, from the non-action of the toning-bath on the parts in contact.

The print must be allowed to remain in the toning-bath till it has acquired a rich violet tint. If purple tones are desired, it must then be removed from the toning-bath and rinsed in water, and then placed in the fixing bath—one ounce of hyposulphite of soda to six ounces of water. It must be allowed to remain in this bath for about twenty minutes, if an albumenized paper: plain paper requires less—from ten to fifteen minutes, according as it is thick or thin. When fixed (which is ascertained by holding the paper up against the light and ascertaining the absence of spots of imperfect fixation), it is placed in a large flat dish, in a sink, with a good stream of water constantly running, for about four or five hours. It may be then be taken out and immersed in nearly boiling water, and then dried and mounted.

I will now describe some of the failures. The most common are the following:—

1st. The print marbled and spotty after toning.

Causes.—A. Badly albumenized paper. B. The print allowed to rise to the surface of the toning bath. C. One, two, or more prints adhering or touching each other so as to prevent the action of the toning bath.

2nd. The print has a cold and faded appearance when finished.

Causes.—A. The chloride of silver in the paper in excess with regard to the free nitrate of silver. B. From too weak a negative being used the light has not had time to cause a vigorous action on the paper. C. Over-action of the gold bath imparts a cold and grey tone to the picture.

3rd. Small specks and spots of various kinds. These, when not corresponding to similar marks in the negative, are usually due to metallic specks in the paper.

Remedy.—Try the effect of keeping the paper a month or two, that the metallic particles may have time to become oxidized.

4th. Marbled stains on the surface of the sensitized paper.

Remedy.—Draw a strip of blotting-paper gently over the surface of the nitrate-bath, and see that the sheet does not touch the bottom of the dish.

5th. Removal of the albumen from the paper during sensitizing, and white deposit in the silver-bath.

Causes.—The bath is probably alkaline, and contains too little silver: add more nitrate of silver, with a drop or two of nitric acid.

6th. The print refuses to tone.

Causes.—A. Long keeping of the proof after printing. B. Too much alkali in the toning-bath.

When the printing bath becomes discoloured by use, Mr. Tunney's method of decolourising it will be found the most certain. It is as follows:—Add one drop of saturated solution of citric acid to the bath, and shake it up. This, if the bath be alkaline, will cause a slight deposit of citrate of silver, and will immediately clear the bath. The solution may then be filtered. If no deposit take place on the addition of the citric acid, it shows that the bath is still acid. In that case, one drop of ammonia added to it will at once produce the desired effect.

THE IODIDES: THEIR CHEMISTRY APPLIED TO PHOTOGRAPHY.

BY PROF. F. A. BOSSARD.*

Some time since I read in a photographic journal the following sentence: "Intensity is not in any manner dependent upon the kind of iodizer used in collodion." Such passage gave cause to the selection of the above title for this article. Repeatedly I have been asked by photographers—"What iodide is best for negative collodion?" It is a question which is, indeed, very important, yet I have never seen it fairly discussed. I will therefore endeavour to answer it, and give my opinion upon the subject to your readers.

An iodide in chemistry is a binary compound, and therefore consisting of two elementary substances. Thus, if we take the iodide of potassium (KI), we find, by submitting it to the action of a powerful galvanic battery, two separate

* From *Humphrey's Journal.*

substances called elements, the base, K, (kalium or potassium), being an electro positive element, is found at the electro negative pole, and I (iodine), performing in this case the part of an electro negative element, is found at the electro-positive pole. The general rule is as follows:—as chlorine acts on a base or other element, so does iodine; and the reaction of the iodides with the metalloids is analogous to that of the chlorides; consequently the manufacture of the iodides is similar to that of the chlorides, with comparatively few exceptions; and the bromides, although analogous to the iodides, yet their manufacture in several cases is entirely different from that of the iodides; as, for instance, bromine combines directly with ammonia to form bromide of ammonium, whilst iodine does not. These electro-positives combine themselves with the electro-negatives according to certain proportions only, and the quantities with which they combine are called chemical affinity, which we divide into two classes—first into single proportions, and second into multiple proportions. To single proportions belong all those that combine equivalent by equivalent, and to multiple proportions those which combine one equivalent with two of the other element, or with 3, 5, or 7, or 2 with 5 or 7, etc. By adding KI to $AgONO_5$, dissolved in HO, we obtain $AgI+KONO_5$ (+HO) or $AgONO_5+KCl=AgCl+KONO_5$. By such a double decomposition we see that silver has a greater affinity for iodine or chlorine than it has for nitric acid. The equivalent of I is =126, and that of K=39; therefore 126 grains of pure iodine require precisely 39 grains of pure potassium in order to be converted into iodide of potassium, and consequently they would give us 126+39=165 grains of iodide of potassium, which amount would be the equivalent of KI. Now let us take the equivalent of KI=165 (say grains), and we dissolve it in some distilled water, and next we dissolve the equivalent of $AgONO_5$ (170 grains of nitrate of silver) in some distilled water; we now mix the two, and we have not iodide of silver alone, but also nitrate of potash; for, since Ag has a greater affinity for I, it combines therewith to form AgI; now, the O of the silver combines with the K to form KO, which the powerful NO_5, that had left the AgO, redissolves, thus forming $KONO_5+HO$. Should the NO_5, which is a powerful agent, not meet the KO to dissolve it, we should introduce into our bath, by every plate we dip, just as much NO_5 as we remove of Ag, or rather the corresponding equivalent weight of the Ag used.

Some operators might ask—"Why should the $KONO_5$ stay in the bath, and not upon the film? or why should the AgI not stay in the bath!" To such I would say, that a bath or silver solution being saturated with AgI renders, of course, the AgI upon the film insoluble, and, it being retained by force of the proxyline in a minute state of division, is rendered inseparable from that film. Should we add too much iodide to the collodion, the consequence would be, that so great a quantity of AgI would be formed as to render it impossible for the collodion to retain it upon its delicate film, and consequently it would, as nearly all operators are aware, burst in particles out of the film. But let us make a solution of 100 to 150 grains of nitrate of silver to the ounce of distilled water, adding nothing else to it whatever; then coat a plate with collodion, dip it into this solution, remove it in a few minutes, and we will find little transparent holes upon the film, which are, in consequence of the silver solution not being saturated with AgI, thus rendering the AgI of the plate soluble in the solution. Put the plate back again into the solution, and leave it there several hours, observing it from time to time, until finally you will find that the AgI has entirely disappeared, and consequently has been dissolved by the $AgONO_5$.

Now the $KONO_5$, being itself soluble in water only, is partially washed off the film by the water in the bath, and when taking up the plate we naturally draw up a little of the bath solution, and there being with it a little $KONO_5$, such action produces a whiter picture, or rather a whiter film. This accounts for the fact, that collodion excited with KI and KBr has more tendency to yield a whiter film than other kinds of collodion. Many operators add $KONO_5$ to their developer in order to obtain whiter films.

Just so it is with the iodide of iron; it yields a white film because it forms the protonitrate of iron, which is known to most operators as a developer which yields fine white films. We certainly must regret the speedy decomposition of the iodide of iron in collodion. I have, however, of late adopted a new plan of obtaining protonitrate of iron upon the film before it is exposed. If I were to dwell upon this important subject now, it would take up too much time. I intend, on a future occasion, to make my new method known.

(*To be continued.*)

Proceedings of Societies.

London Photographic Society.

The first monthly meeting after the summer recess was held in King's College on the evening of Tuesday, November 5th. The Chief Baron in the chair.

The minutes of the previous meeting having been read and confirmed.

The Secretary read a letter from Mr. T. Ross, accompanied by a series of pictures taken by Mr. Harral with one of the panoramic lenses. The pictures included an angle of 100° on the horizontal line; the curved glasses were made to include 110°, and by very clean manipulation a picture having 105° might be obtained perfectly defined.

A letter from Mr. Dallmeyer was read, accompanied by a series of landscape specimens, chiefly by Mr. Wilson, taken with the triple achromatic lens. Its copying powers were well known and recognized, and these were intended to illustrate its landscape capabilities. The pictures included a very wide angle perfectly defined, were entirely free from distortion, and, some of them being instantaneous, showed the rapidity of the lens. The Chief Baron called especial attention to the exquisite delicacy and detail which characterized the pictures by the triplet lens.

Mr. Baynham Jones sent a letter and some specimens taken with an ordinary landscape lens. The lens had the focus of five inches, and the pictures were six inches long, including an angle of upwards of 60°.

Mr. Gordon Thompson sent a letter calling attention to the contemplated exhibition at Bradford.

Mr. Vernon Heath exhibited a series of views in Perthshire, On the Thames, &c., of which we shall speak next week.

Mr. Dallmeyer exhibited an instantaneous shutter for his stereoscopic lenses, the chief distinction of which was, that instead of having, as was usual, two distinct motions, one up and one down, the uncovering and covering of the lens was effected by one continuous motion. It also had the advantage of giving the greatest exposure to the fore-ground by first uncovering the lower part of the lens. It had been tried, he observed, and found effective. We will describe it in detail next week.

Mr. Shadbolt said it was an error to state that the fore-ground would receive the most exposure. Uncovering one part of the lens before the remainder would only act like placing a stop before it; the whole of the picture being exposed through that part.

Mr. Dallmeyer said surely Mr. Shadbolt misconceived the question. If he observed the motion of the shutter he would surely perceive that the lower part by which the foreground was depicted was uncovered first.

Mr. Shadbolt reiterated that it only acted as a diaphragm, reducing the aperture, and therefore giving less light to all the parts of the image.

The Chairman remarked that half a lens would give the whole image.

Mr. Dallmeyer said this would be the case with a single lens, and in regard to central pencils, but not so with regard to ex-centrical pencils. This shutter was, however, designed for use with his combination lenses.

Mr. Shadbolt said that if used with a portrait lens, it would, as Mr. Dallmeyer stated, expose the foreground first.

The thanks of the meeting were given severall t o the gentlemen who had exhibited their specimens.

Mr. J. A. Malone then read a highly interesting paper on the constitution and toning of the photographic image, illustrated with experiments, tending to prove that the image in the print is simply reduced silver in a fine state of subdivision (see p. 527). The thanks of the meeting having been awarded by acclamation.

The CHAIRMAN expressed the great pleasure he had felt in listening to Mr. Malone, and hoped they would shortly hear the results of his further experiments. He had been struck whilst observing the beautiful experiment of such a heavy substance as gold, held in suspension by the minute division of its particles, by the thought that it threw some light on the principle upon which the clouds were suspended in the atmosphere.

Mr. MALONE thought there was no doubt the clouds were composed of particles of water in a minute state of subdivision; not even in small bladders as had been stated.

The CHAIRMAN said that notion was the most absurd conceivable, notwithstanding that one person had said he had seen them. The theory Mr. Malone had put forth was moreover beautifully analagous to many other cases in which the state of minute division of bodies influenced their colours. He had pleasure in announcing to the meeting that sometime during the session, Mr. Warren De la Rue would give them an account of his visit to Spain, to photograph the sun during its eclipse. He could not help here remarking that he had more than once expressed a hope and conviction that photography would be a valuable means of extending our knowledge of the properties of light, and of detecting facts in connection with the sun, which at present we did not suspect. Mr. De la Rue had already shown that when the human eye was blinded with excess of light, photography could seize and delineate what the human eye could not perceive, and thus aid us to knowledge of the natural history of the sun, unattainable by any other means.

The SECRETARY then read a lettter from Mr. Rouch, enclosing a contribution to the Archer Fund, from the Photographic Society of Victoria, amounting to £5.

After the usual votes of thanks the proceedings terminated.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 6th November, 1861.

THE protracted season of fine autumnal weather has had the effect of detaining photographers in the provinces beyond the period usually fixed for the resumption of their weekly *séances*. The first meeting of our photographic society after the summer vacation, was appointed to take place on the 18th of October, but the attendance was so small that it was deemed expedient to adjourn the sitting to the 8th instant.

Yesterday an exhibition was opened at the Society's rooms, Rue Drouet, of the prizes in the lottery, the proceeds of which are to be devoted to a fund for premiums and awards for the encouragement of the art of photography, and which will enable the Society to organise another exhibition.

The season for practical photography has at length drawn to a close, after as favourable a summer as operator could desire. The fruits you will doubtless see at next year's Great Exhibition. But if the opportunity for practical essays now fails us, we can profitably recur to the the theoretical, and furbish up our old formulæ, methods, and processes, and give them a new gloss. "There is nothing so new as that which is forgotten," and many an unfertilized hint may be picked up among the leaves of an obsolete essay or manual. There is a fever of fashion in photography, as in most other pursuits: one day albumen is in the ascendant, at another it is waxed paper, then a mixture of both. Collodion, however, has managed to over-ride all other media, and seems in no present danger of being superseded. Were it less capricious and more manageable, under certain conditions of difficulty, it would be unexceptionable as a medium, and it is to be hoped that there is something really tangible in M. Garneri's proposed "mineral collodion." Viewed theoretically, this new medium looks promising. Hydrated silica, in a nascent state, is a substance whose properties are only imperfectly known. There are, however, numerous examples of the exceedingly great hardness it gradually acquires in the course of time, surpassing in that respect even glass, and almost attaining that of precious stones; a power of resisting scratches with the nail is not beyond the limit of possibility.

At a high temperature, and consequently under a great pressure water appears to be a solvent of silica, and this is the principal cause of a great number of silicious formations in tertiary strata from which mineral waters flow. But this solvent power of water upon silica is not available for photographic purposes, inasmuch as it only takes place at high temperatures, and ceases upon cooling again; but there exists a substance which has quite a special affinity for silicum, the radicle of silica, and forms with it a volatile body, a real gas; this substance is fluorine, which is known only in its combination with hydrogen, as hydrofluoric acid. This acid, which is extremely caustic, attacks silica either alone, or combined with the alkalies and earths, which gives to it the singular property of corroding glass, and rendering its surface rough, or "ground." In this action fluoride of silicum is formed, which in a dry state retains its gaseous form, like hydrochloric gas, but in contact with water, the latter is decomposed, and gives rise to the formation of silica and hydiofluo-silicic acid, which remains dissolved, and forms a very stable body.

In his mineral collodion, M. Garneri has taken care to introduce hydrofluo-silicic acid, which combines with a portion of the alkali, and remains suspended in the liquid in the state of hydrofluo-silicate. This is removed by filtration, and the filtered portion only, composed mainly of dissolved hydrated silica, is reserved for use.

In all probability there remains with the silica a portion of the anterior compounds which hold it in solutions, and we must seek the means of rendering this state permanent, under the influence of time and atmospheric changes.

The alkaline hydrofluo-silicate remains upon the filter in a gelatinous form, exactly resembling collodion coagulated by matter; but contrary to the latter (which requires to be deprived of all its water to be dissolved anew in alcoholized ether), it is sufficient to add an active body to dissolve it afresh; since this new collodion has water for a base, and not alcohol and ether, like ordinary collodion.

Like the collodion at present in vogue, this new collodion must be iodized. It is not a matter of indifference what iodide is introduced, as its solution is effected by the collodion alone, and gives the stability desired. The solvent must belong to the neutral class of bodies, and acid rather than alkaline to act with the silver bath. The alkaline fluorides present the greatest chance of success.

This mineral collodion must give as uniform a film as albumen, and not granulated like collodion. For large pictures, and especially landscapes, the 'grain' of collodion is not objectionable, it give more lightness and atmosphere to the picture; but for negatives of small dimensions, the fineness of the sensitive film can never be too great.

The mineral collodion can never present the greasy aspect of our present collodion, which is the cause of so many spots and failures; and this characteristic will facilitate, under all circumstances, its absorption and washing, to operate with it in the dry state. In this state some facilities will be required to preserve its sensitiveness. Ordinary collodion acquires a horny nature very rapidly, which impairs its porosity; with the mineral collodion we may expect that the water will leave it very slowly, and that its porosity will continue indefinitely.

The solvent of the mineral collodion being water, a very great facility will exist for adding the salts intended to produce a given effect, and doubtless it will adhere very tenaciously to the glass plates.

Photographers and astronomers are on the *qui vive*, making their preparations to observe the eclipse of the sun of the 31st December next, to which the recent discoveries by MM. Bunsen and Kirchoff in celestial chemistry impart a new and additional interest.

One point to which observation will be specially directed, is the examination of the spectrum of the corona, with which the moon will be surrounded for a moment, in that portion nearest the sun, to see if this aureola exhibits an inversion of the ordinary solar spectrum, or not, that is to say, whether Frauenhofer's rays will be replaced by brilliant lines.

Since the publication of the labours of MM. Bunsen and Kirchoff, the question of a solar atmosphere has acquired a basis, and is susceptible of proof by direct experiment. If, for example, the spectrum of the aureola which will be produced on the 31st December next exhibits to us an inversion of the solar spectrum, the much vexed question will be solved, and the existence of a solar atmosphere will become a definite scientific fact. If the contrary should be the case, we may be compelled to admit that absorbtion takes place in the substance of the photosphere, the surface of which emits, not only all the rays, but which doubtless contributes to the light of the sun by a part of its thickness; whichever it may be, the experiment is not impracticable, as it has already been performed. Sig. Fusinieri, of Vicenza, on the occasion of the magnificent solar eclipse of 1842, analysed the spectrum of the aureola. It appears, however, that he did not attach that importance to it that recent discoveries have now rendered evident. He contented himself with remarking that *green* was entirely absent from the spectrum of the aureola. The season at which the coming eclipse takes place does not encourage the expectation of fair weather; but we *hope for the best.*

MODIFIED RESIN PROCESS.

5, *Aberdeen Park, Nov.* 1*st*, 1861.

Dear Sir,—During the last fortnight, I have been making experiments with gum guaiacum as regards its use in the dry processes. I prepared the plates by two methods.—1st, adding the gum to the collodion; 2nd, coating the sensitized plate with an alcoholic solution of the same. The result in both cases was fine, brilliant, and intense negatives, and the film is so hard that any deposit may be rubbed off without any danger of tearing. I myself give the preference to the first method, as it is rather more simple than the second. The only thing to be determined is the keeping qualities of the plates, and whether the gum has any action on the nitrate bath.

I give my manner of working, as I think it is the best for securing successful results. First, Dissolve gum guaiacum in alcohol, filter, and add to suitable collodion, (I used Ponting's,) in the proportion of one grain to an ounce of collodion, well shake, and allow it to settle for two or three days. Having coated and sensitized the plate, which must be perfectly clean, place it in a dish of *distilled* water, until another is ready. Now remove to a large pan of water, and let it remain there for half-an-hour, then finish with a few drams of distilled water; dry by artificial heat.

Expose about the same time as for a tannin plate; thoroughly wet the plate, and develop with pyrogallic acid, 3 gr., citric acid, 1 gr., acetic acid, ½ dram, water, 2 oz.; though, I daresay, gallic acid and protosulphate would answer, but I have not as yet tried them.

Having poured the developer over the plate till all greasiness has disappeared, add a few drops of a 20-grain nitrate of silver solution. When all detail is brought out, add more nitrate, till the requisite intensity is gained. Fix in hypo, and when the plate has been well washed and *dried*, float it with alcohol to dissolve out the small quantity of gum, which, if allowed to remain, would render the plate slightly opaque: dry and varnish.

Second. Having proceeded in the same manner as in the preceding, but without the gum in the collodion, as far as the final washing, place the plate in a dish of alcohol till the greasiness disappears, then remove it, wipe the back, and coat it with a filtered alcoholic, 2 gr. to an ounce solution of gum guaiacum.

Expose, develop, &c., as in No. 1.

No. 2 will be most suitable for those who only wish to try a plate; but it is diffcult to get an even coating of the gum. Hoping your experimental readers will give this process a trial, I am, your's respectfully, H. Cooper, Jun.

DAGUERREOTYPE ANTICIPATED.

Dear Sir,—I read in a recent number of your valuable paper "Electric Telegraph anticipated," and thinking that the above title may also be of some interest to your numerous readers and my brethren photographers, I beg to state that in a French book, "Les fables de Fenelon," which has apparently been written for the education of the Duc de Bourgoyne, grand son of Louis XIV., in an able composition under the name of "Voyage supposen 1690," and amongst the many wonders of which the fable is made up, we read:—"Il n'y avait aucun peintre dans tout le pays, mais quand ou voulait avoir le portrait d'un ami, un beau paysage, ou un tableau qui representât quelque autre objet, on mettait de l'eau dans de grands bassins d'or et d'argent; puis ou opposait cette eau a l'objet qu'on voulait peindre. Bientôt l'eau, se congelant devenait comme une glace de miroir, ou l'image demeurait ineffaçable. On l'emportait ou l'on voulait, et c'etait un tableau aussi fidele que les plus poli glaces de miroir."

There was no painter in the whole country (the Island of Wonders); but when the people wished to have the likeness of a friend, a fine landscape, or a picture representing some other object, they placed some water in large basins of gold or silver, then they brought this water opposite the picture they wished to take. Soon, the water in congealing became similar to a looking-glass where the image of that object remained fixed; they carried it where they wished, and it was a picture as faithful as if reflected from the best polished looking-glass.

How far from thinking, the noble and virtuous Fénélon must have been, when writing the above, that such a fabulous wonder might one day be no longer a fable, but a reality!!!

How glorious is the art through which such wonders are operated!!! C. de Langue

Swansea, October 23*rd*, 1861.

Photographic Notes and Queries.

Tannin and Tobacco.

Mr. Editor,—One of your contributors informed his brother photographers that cotton wool, "*steeped in a solution of tannin, will remove all the nausea and hot flavour of tobacco.*" As a smoker, and reader of your valuable paper from its first number, I beg to inform you that I steeped cotton wool in a strong tannin solution, and applied it as directed, but it failed to produce the effect desired.

As I am a *cigar* smoker, preferring a pipe could I meet with an antidote for the heat and nausea named, I should esteem it a great favour if you could give me a hint on the subject, and oblige, yours respectfully, Henry Rose.

Newcastle-on-Tyne, October 22*nd*, 1861.

[We know of no method of obviating the "heat and nausea" produced by tobacco, except avoiding its use where these results are produced. Rejlander showed us one day his fine photograph of "The Goddess Nicotina," a shrivelled old hag, hiding her hideous face with a fair mask, as she offers the fragrant weed to a youthful votary. We asked him, "Do you smoke?" With a comical shrug, he answered, "I do." We feel a somewhat similar feeling to Rejlander in suggesting this mode of avoiding the unpleasantness referred to. But we never smoke when it causes "heat and nausea." That should be a sign to any one that it is injurious. But this is not photographic! —Ed.]

Preserving Prints.

Mr. Editor.—It is a source of grief to me to know that photo graphs, as a rule, fade and decay.

One great cause of this arises from atmospheric influence, damp, noxious vapours, &c., &c.

It has often struck me, that the most effectual way of checking this would be to use sheet gutta percha, about the thickness of four-sheet mounting board, cut about a quarter of an inch longer than the glass; place the mounted photograph face to the glass, put a piece of card against that, reverse all three on the sheet gutta percha, warm the edges, and lap them over on the glass.

"Where can I procure the kind of sheet gutta percha I require?"

The edges of the glass may be roughened, or varnished, to make it adhere, if there should be any difficulty in that.

I want to see the air perfectly excluded from the photograph—hermetically sealed.—I am, Mr. Editor, yours faithfully,

Cheltenham. AN ARTIST.

BLACK PAPER FOR TRANSFERS.

SIR.—Can you, or any of your correspondents, put me up to way of making black albumenized paper?

I want it for transferring glass positives, as I cannot procure any glazed paper of a sufficiently fine surface at any stationer's in this place; and it strikes me if a black albumenized paper could be made it would answer admirably.

I have tried the process, given in the NEWS some time back, of making black glazed paper, but it does not answer my process of transferring, being prepared with oily substances.

I think, sir, if you will kindly insert this application, some of our friends will assist me; or perhaps inform me where a good glazed paper suitable for the purpose may be obtained,—I am, sir, your obedient servant, J. C. V.

[Albumenized paper may be sensitized and then blackened by light. We know of no better method.—ED.]

COMMON WATER FOR THE SILVER BATH.

SIR,—In your notice "To Correspondents," my attention is just drawn to your reply to M. D. in this week's paper. In division 3 of that answer you state "Mr. Fry published a method of making the silver bath so that it should *not discolour*, which consisted in the use of common instead of distilled water, and never filtering out the precipitate; but always leaving it in the bottle, and shaking up with the solution."

Allow me say that I am unfortunate enough to find that this is an entire mistake. About ten days since I set up a new bath for printing, and used *common water* instead of distilled, with 90 grains of silver to the ounce, and a few drops of acetic acid (about 5 to each ounce). I was induced to make my bath thus as I had heard it would be so simply cleared, by merely shaking up the precipitate and allowing it to settle after using the bath with albumenized paper, that the precipitate would carry down with it, in fact, all impurities and discolouration. I had pleasing visions of no more kaolin, no further use of filtering paper, and loss of silver thereby, no washing of filter after every preparation of paper. I made my bath *in quantity* double what is needful for filling sufficiently my porcelain tray, in order that I might pour as much as was required out of the bottle, without disturbing the sediment at the bottom, and filtering it, mixed with the fluid about to be used; but all is to no purpose. I used the bath first and last on Monday, and shook the precipitate well up (together with a fresh addition to keep up strength and quantity), with the fluid after use. Four-and-twenty hours after, I looked at it, it was *very yellow*, and beaded with little bubbles at the surface, which no exposure to the air would dispel. Before sitting down to write this, I have looked at it again, it is still *as yellow as ever*, and the air bubbles *as they were*. If five days won't clear it, I may reasonably infer no time will suffice; so that I must again revert to kaolin and filtering paper. I send this in the hope that, perhaps, you may be able to suggest some remedy; and if not, to warn any against being misled or disappointed.—I am, sir, yours obediently, D. H. F.

October 26th, 1861.

[We have never tried making the silver bath with other than distilled water ourselves, as we rarely make a new one, continuing to refresh the old solution from time to time. We know that in Mr. Fry's hands his method answers. But common water is a very vague term, and as it designates a very variable fluid, constant results can scarcely be expected. Mr. Fry does not add acetic acid, and that may in some cases tend to vitiate the result. We prefer a printing bath slightly acid with nitric acid.—ED.]

ALABASTRINE SOLUTION.

SIR,—The following Alabastrine solution is equal to any sold. Make a saturate solution of bichloride of mercury in distilled water. Take 2 ounces of this when clear and bright, and drop in 3 drops of strong ammonia; re-dissolve the deposit by dropping in muriatic tincture of iron, from 12 to 20 drops, more or less; let it stand a short time, and remove the red colour by adding 3 drops of nitric acid.—Yours very respectfully,

JOHN HUDSON.

62, *Queen Street, Hull, Nov.* 4, 1861.

IODIZING THE BATH.

SIR,—Would you be so good as to tell me why it is that when I strengthen my bath, by the addition of silver, from one of the first establishments, the plates for the first minute or two after insertion begin to get creamy, as they should do; but when I remove them after two minutes, the creaminess has partly disappeared, and they become transparent about the edges; and if left a little longer in the bath, they become perfectly transparent. To correct this, I weakened my bath again by the addition of water, and experimented on several plates. They now remain longer in the creamy state, but not quite to my satisfaction.

What I wish to know is, whether it is the bath being too strong would cause this, or is it the insertion of experimental plates which partly restored the bath? This has happened to me more than once, and I cannot find it noticed in books on the subject.—Your's, &c., A SUBSCRIBER.

[We insert this note here, instead of answering it in another page, because we have reason to believe, from the queries which reach us from time to time, that the subject is not understood by many young photographers. A certain amount of iodide of silver is soluble in a solution of nitrate of silver of a given strength; if the strength of the silver solution be increased, more iodide of silver will be dissolved. Thus when more silver is added to a bath, or when a strong fresh solution is added, it is well to put a large coated plate in the bath, and leave it there for an hour or two. The iodide of silver formed will quickly be re-dissolved, and by these means the fresh solution will become sufficiently saturated. By weakening the bath, its capacity for dissolving iodide of silver is lessened, and excess of iodide in a solution may be thrown down by adding water. Whenever the plate on removing it from the bath is found all transparent, or with transparent streaks, spots, or patches, the probability is that it arises from this cause: the solution is insufficiently charged with iodide of silver; and it will dissolve the iodide of silver formed in the film, unless the plate is removed as soon as the film is creamy, so long as it remains unsaturated.—ED.]

Miscellaneous.

THE EYE AND VISION.—Although we derive so much pleasure and obtain so much knowledge through the sense of vision, very few persons are really acquainted with the powers and peculiarities of the eye. Thus our range of vision is bounded by the projecting parts of the face. In relation to this Dr. Alfred Smee says:—"If the eye be steadily directed toward one point, it is sensible of the presence of objects over a vertical range about 121° and a lateral range of about 149°." But perfect vision is only obtained over a range of about 2° 18′, which in practice is in the relation to the distance of the object to be viewed as 1 to 25. Thus at 25 inches distant, a person will be enabled to read a word one inch long without the slightest motion of the eye, and at twelve inches distant a word half-an-inch long may be read in the same way. Where the optic nerve penetrates the eye, the retina is insensible to light, which causes a total loss of vision over about 6° 20′—the commencement of the insensible spot being 12° from the centre of vision. As the result of this there is a portion of the field of view, equal to one-eighth the distance of the object, which is utterly lost: and though it seems at first thought incredible, it is nevertheless true, that in regarding a range of hills eight miles distant, one mile of the range is not perceived by the eye.

Talk in the Studio.

Obituary.—We regret to announce the death of Mr. Clarkington, well known for many years past as one of our most enterprising and successful metropolitan photographers. During the period when the Daguerreotype was in the ascendant, he practised that process with considerable skill in the Strand. Subsequently he removed to the Quadrant, Regent Street, and obtained some reputation for a superior class of coloured glass positives, for which he had a large demand. His premises being required for the erection of St. James's Hall, he removed to the studio he occupied up to the present time, known as the "Sponsalia," Regent Street, the glass room and appointments being amongst the best in London. He took the tide of the "cardomania" at the flood, and has, we believe, been very successful in the production of public characters. He died on Saturday last, the cause being, we understand, disease of the heart.

To Correspondents.

Syrinx.—The acetate of soda and gold toning bath may be used immediately it is mixed; but it is usually better to keep it for 24 hours. There are many excellent points in the glass room to which you refer, and it is in the main right in principle. We cannot, however, criticise it in detail here.

G. H. C.—We cannot advise you as to the best and cheapest house for cardboard mounts, except by recommending you to examine our advertising columns from time to time. Questions of price do not legitimately come under our attention.

Puzzled.—We have not had an opportunity of trying the No 2 lens of the maker you name, but the No. 1 B of the other maker we are in the constant habit of using, and find its results, in all respects, perfectly satisfactory.

F. Lane.—The glass was safely received. The report will appear in the usual place next week. A hasty examination seems to indicate that it is satisfactory.

Inquirer.—The photoglyphic process is not, that we are aware of, practised commercially. We are not aware of any specific progress recently. Photolithography has made considerable strides, and for all purposes in which the subject is represented in lines or points, not in "tints" or half tones, it may be regarded as perfect. A stone would yield, we apprehend, considerably more than four hundred prints. See the specification of Messrs. Beattie and Alexander, in a recent number. The most promising carbon process of which we hear anything is Fargier's, described from time to time in our columns. The specimens by it, now exhibiting in the French Exposition are, we are told, very fine.

Aspirans.—The plan of increasing intensity in negatives by adding gutta-percha to the collodion, has long since been abandoned. The proper method of regulating the intensity of the collodion depends mainly upon the pyroxyline. Other circumstances will affect it, but any amount of intensity may be secured by suitable pyroxyline. The method of sensitizing, the condition of the bath, the kind of developer, will, however, materially modify results. Pyroxyline, made at a high temperature, and with weak acids, will aid intensity; the use of iodide of potassium, without much bromide, will aid intensity; organic matter in the bath, and in the developer, will aid intensity; but in all cases care must be taken not to secure intensity at the expense of half tone.

C. E. L.—On adding oxide of silver to a bath containing acetic acid, acetate of silver will be found. You can, after sunning the bath, add a little nitric acid if you please, that will just have the effect of decomposing the acetate of silver, and freeing acetic acid; the oxide of silver will then combine with the nitric acid and form nitrate of silver, leaving the bath, provided you do not add too much nitric acid, in the same condition as regards the nature and amount of acidity, as at first. The addition of the oxide in the first instance will, however, allow any organic matter present to be more readily thrown down by light.

F. Y.—The amount of subscription for the Photographic News and postage to Malta, for one year, will be 17s. 4d. Vol. 3 only can be had. Lamp black is better for painting out skies than indian-ink. The latter is a somewhat transparent pigment, the former is more opaque. We prefer masking a sky, where it is necessary, to painting out, as there is less danger, if care and skill be used, of getting hard outlines.

W. Bartholomew.—The parcel has arrived, and we will have pleasure in trying the plates and reporting upon them shortly. The others we tried and found very good, the development quick. We are glad you find the plan of developing without adding first, so satisfactory. It is our conviction that it will prove a very valuable aid to softness in all dry processes.

W. Larchin.—In the Photographic Exchange Club you can send any reasonable number of prints from the same negative if it be very fine. But as a general rule it is well to send variety. Send, in short, as many as you can of all your best pictures. If each member do this, a brisk and satisfactory series of exchanges may be kept up. You must write to the secretary to place your name on the list. We are glad our suggestion made your collodion give good results.

J. C.—If you find your lenses work satisfactorily, there is no reason for changing. We have met with many good French lenses. Our answers to correspondents who consult us as to what they shall purchase, have simply intimated that cheap French lenses might chance to turn out either good or bad, there was no certainty. Those purchased of the dealer you name will probably be made in France; but by whom we have no idea. The qualities will probably be variable. They have no reputation that we know of, either good or bad. 2, Those of the English maker you name will doubtless be much superior in every respect. 3. The most rapid lenses we know, or have tried, are the B lenses of the maker you mention. Of the specimens you enclose, the card portrait taken with the half-plate is the only one which speaks favourably for the lens. The others, if they are the best results as regards definition, which the lenses will give, suggest that they are very faulty. The card picture by the half-plate is very good indeed.

A. W. F.—Your manipulations, as described in your letter, are in the main right. The cause of fading is, however, probably imperfect fixation. One part of hypo in six of water is weaker than we like. One part in four or five gives the weakest solution desirable for safety. Five or ten minutes will be in many cases decidedly too short a time for immersion in the fixing bath, with many samples of paper. See our answer to M. A. last week. Take care that your hypo solution is fresh, and that the toning solution is not at all acid.

W. R. A.—The silver bath for working Mr. Richards's Albumen Process should be saturated with iodide. Whatever proportion of iodide of potassium you use, you can only saturate the solution; any excess will be precipitated, and must be filtered out. You will find the modification of the albumen process there given as simple and efficacious as any that has been published.

W. S. H.—We shall have a paper on the subject very shortly. Should it not be ready soon, we will write to you, and describe details. We shall have great pleasure in receiving the article of which you speak: the subject is very interesting, and not exhausted. We should be glad to know the lens with which the vignette sent us before was produced

E. H. B.—We have repeatedly described the method of forming oxide of silver, lately; but will once more repeat it. Add, a little at a time, a solution of caustic potash to a solution of nitrate of silver, until all the silver is thrown down. The precipitate will be a dark insoluble powder of a brownish olive tint, which is oxide of silver. Wash well in water to remove the nitrate of potash formed, and the oxide is ready for use. 2.—You will be perfectly safe in sending direct to the manufacturer you name. For his reputation's sake nothing will be sent out which is not as perfect as it can be made. Besides, he is a highly conscientious and honourable man.

J. T.—We are obliged by your communication, and the filtrate enclosed, which we will examine at leisure. The greatest evil which might have been apprehended, but which it appears you have not experienced, would arise from the large extent and diversified character of the adulterations, with which commercial cyanide is combined.

N.—We are obliged by your communication and the plate-holder. We see no reason why the letter should not appear in our next in its entirety; as the subject is necessarily interesting to a large class of amateurs. We will bring the model and the letter under the attention of some manufacturer. We will now examine the prints. The stains might unquestionably be caused by "contagion;" but that contagion is chemical action, and it is always worth while to ascertain, if possible, its cause. The print enclosed, excited on a 90-grain solution, is certainly not so rich as the others from a weaker solution; but were all the other conditions the same?

Stereo writes to express entire satisfaction with the new arrangements of the Photographic Exchange Club. The slides enclosed are very good: a little more warmth in tone, would be, however, an improvement. There is, however, a slight inclination to yellowness in some parts, which is suggestive of sulphur action, or imperfect fixation. Do you keep your hypo solution perfectly neutral? The prints of the professional photographer whom you name, are decidedly sulphur toned, and show rapid signs of fading. We are obliged by the other parts of your communication, some of which we will use.

N. X.—There are several modes of toning; but none so satisfactory in all respects as by gold. 2. Camera makers and lens makers generally reckon from the back lens when they are speaking of focus. The equivalent focus of a portrait combination lies somewhere between the front and back lenses, varying in position with the kind of lens. 3. If a lens cover a space of 5 by 5 perfectly, it will cover well for card portraits. 4. Moule's preparation for burning in the photogen is as good a white fire as we know: It is stated to be composed of nitre, sulphur, and orpiment; but in what proportions we do not know.

H. C. H.—The amount of capital required, and the amount of success which may be hoped for, depend entirely upon circumstances, to which it is impossible to refer in general terms. Much depends on the locality, on whether suitable premises are found ready to hand, or whether glass-house is to be built, &c., &c., &c. From £50 to £500 might be required in a moderate business; and with good work, and good business tact, there is, we believe, plenty of room for success.

W. S. Parry.—We are much pleased with the specimens received. The card portrait of the lady is decidedly amongst the very best we have seen. Soft, delicate, and vigorous, pure in tone, easy and natural in pose, expression, and general arrangement.

F. E. G.—You forget that several formulæ may each be right, all giving slightly different results, each operator selecting that which he likes best. The tones of the prints enclosed, are warm and pleasant. The horse pictures are good, but the lenses have been a little over-tasked, and apparently with full aperture. 2. It is impossible to tell you how much oxide of silver will be necessary to neutralize your bath, because we don't know how much acid is present. Add excess, and all that is not required will fall down, and can be filtered out. If acetic acid be present, acetate of silver will be formed. 3. To convert an old collodion bath into a printing bath, first precipitate the iodide with citric acid, as described in a recent article, and then boil gently in a glass vessel until it is reduced to half its bulk.

C. N.—The first maker you mention we consider best. Of those mentioned and numbered in the latter part of your letter, some are not makers, and we cannot speak with certainty of the others; but we have heard good accounts of that numbered 2.

A Searcher asks us to give him instructions how to take a good negative with the solutions required for doing so, and for printing. We can only advise him to read carefully the articles in our pages, from week to week, as the instructions he asks would more than fill a good many such columns as we devote to these answers. In working the positive process and intensifying with mercury as mentioned, the chief difference in manipulation between obtaining a positive and a negative is that the latter will require more exposure. In toning, use the gold solution first, and when the toning is completed, then fix with the hypo solution. If our correspondent will state his special difficulties, we will have pleasure in helping him; but we cannot do him much service when he asks in general terms how to take negatives and print from them.

Some other correspondents in our next.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 167.—*November* 15, 1861.

M. JOUBERT'S ENAMEL PHOTOGRAPHS.

The art of producing photographs enamelled, or burnt-in, on glass, patented little more than twelve months ago, has, in M. Joubert's hands been making steady and satisfactory progress since that time.

On Saturday last a number of connoisseurs and amateurs assembled at Porchester Terrace, by invitation from M. Joubert, to a private view of specimens illustrating the progress and present state of the art. The pictures consisted of between seventy and eighty examples of different styles, comprising reproductions of photographs, portrait and landscape, and of copies from engravings and lithographs, in some cases produced direct from the print, which has been made to serve as the *cliché*, and in other cases from photographs of the prints. They were arranged around M. Joubert's glass-room in contact with the glass, giving a highly ornamental effect of illumination, not easily distinguished from that of stained glass.

The most striking advance which has been made, is in the successful production of a variety of colours. We have remarked in former notices that so far as the production of enamelled transparencies in monochrome was concerned, considerable perfection has been attained. In this respect there is an accession of delicacy and detail; but as regards the question of colour, the progress has been very great, many of the specimens presenting the effect of exquisitely coloured paintings on glass. To some extent, indeed, they must be regarded as such, being literally tinted photographs in enamel colours. Those of our readers who have taken any interest in the process, will remember that the image is first produced by the action of light, through a *cliché*,* on a preparation of some of the chromic salts and organic matter, such as albumen, honey, &c. The effect of this is to produce a slightly indicated image, which is made fully visible, or as it may be termed developed, by the application of a very finely powdered enamel colour. This powder adheres to the parts which have been protected from the action of light just in the direct ratio of that protection. On the lights of the picture, where the light has acted fully, the preparation has entirely lost its adhesive or sticky character, and the powder does "take" to those parts; where the light has acted slightly, a slight amount of powder adheres; and in the deep shadows, which have been perfectly protected by the opaque parts of the *cliché*, the greatest amount of powder, giving the greatest depth of colour, becomes intimately combined with the preparation. We have briefly referred to the principle of operation, in order to explain that, in a variety of ways, a skilful manipulator may, instead of using one powder of one tint, apply many, each in its proper relation, in fact, producing on the photograph an enamel painting. It is unnecessary to enter here into a consideration of the modes which may be, or are, adopted in effecting this, or of the method of dealing with the pictures in many colours in the process of burning in. We merely wish to illustrate how it is that enamel photographs can be produced in the varied tints, which rival painted glass in brilliancy and colour, whilst they far surpass it in truth, and also in facility of production and cheapness.

There were some good specimens of portraiture; but we do not consider that in this department the strength of the process lies. Transparencies, either in colour or monochrome, are not suited to portraiture, their especial object being for purposes to which we consider portraits entirely unadmissible. We can scarcely understand the sentiment which would place the portrait of one well-loved or much-esteemed to the "base uses" of ornamenting a lamp-shade, or ornamenting a library window. The portraits here exhibited, however, show the capabilities of the process in rendering whatever may be in the negative. A striking and effective portrait of the late Douglas Jerrold, from a negative by Dr. Diamond, is amongst the specimens.

Amongst the specimens which favourably illustrate the suitability of the process for the reproduction of figures are copies from several of the well-known and highly artistic *genre* groups of M. Silvy. One of them, already familiar to photographers from having been issued as a specimen of M. Joubert's "phototype" printing process—the "publication of an *Ordre du Jour* in Paris during the Italian war"—is very excellent. The fine light and shade which distinguishes the original picture is accurately reproduced, the most exquisite transparency distinguishing the deepest shadows. A group entitled "Spring," and another "The Savoyards," both photographed from nature by M. Silvy, are also very fine.

Amongst the most successful landscapes are some from photographs by Mr. Mudd. Of these we have in one instance the reproduction in monochrome, and a second in natural colours. The subject is a "Scene in Lancashire." We have before seen some of Mr. Mudd's pictures coloured, and remember to have observed that we preferred the untouched photograph to the effect then produced. We are bound to say, however, that here the colouring is a great improvement. Some slight additions in making out form have been made by the artist in colouring, but without interfering with the keeping or *vraisemblance*. The subject is an autumnal landscape, in which the rich warm browns, yellows, and greens, prevail in all varieties, and present no indication whatever that the process is bound by a limited scale of colour. Wortley Hall, Lancashire, is another effective reproduction from one of Mr. Mudd's pictures.

Amongst the miscellaneous reproductions of photographs from nature, one of the finest is a view of Dordrecht. This is an exceedingly satisfactory picture, with an excellent atmospheric effect. A "Shady Lane in Surrey," is also very good. A group of sheep, coloured, and in monochrome, may be regarded as amongst the most successful and pleasing pictures exhibited. The coloured group, which is worthy of Sydney Cooper, appears to have required comparatively little work from the hands of the artist, the admirable tint in which the uncoloured picture is produced, so pre-eminently suits the character of the subject. A "Quiet Dell in Yorkshire" is very pleasing. A "Scene at Bayswater," is an excellent picture, and a very fine enamel. "Dead Game," is a fine specimen of the rendering of delicate half tone. "Lincoln Cathedral" illustrates the admirable suitability of the process for architectural subjects: this is an exceedingly good picture, and leaves nothing to be desired.

On the whole we prefer the reproductions from photographs to those from engravings. Of the latter there are, however, some very fine examples. A very charming picture, apparently from a lithograph, is a "Mare and Foal." This is a coloured picture, but has apparently not required a great deal of labour from the hands of the artist; the dappled grey of the mare being beautifully rendered by the neutral tint of the enamel.

* We adopt the useful French term, as more suitable here than the term negative, a transparent positive being really used as the source from which to reproduce.

An especial feature of the uncoloured pictures is the variety of tones which prevailed, varying from tints of sepia and bistre to black. In many cases the application of these tones was pre-eminently well suited to the sentiment of the subject, and thus gave great value to the picture. This is a point to which too little attention is given by photographers, many of whom are in the habit of aiming at one especial tone, which is adopted in all cases, for the portrait of a delicate blonde, as well as that of a swarthy brunette; for a landscape in the early grey of morning, or the mellow warmth of evening, and representing spring or autumn, summer or winter. The suggestive value of tone is thus often entirely overlooked, and an important element of effect quite lost. The subject is well worth careful attention, and we take the opportunity in passing, to commend it to the thoughtful and artistic photographer.

If any of the specimens fail at all in effect, it is, we fancy, where the original was not either good in itself, or well suited to the process. Perhaps the chief matter for surprise is not that any of them should be from inferior photographs, but that such a number of excellent specimens should have been produced in a short time. We hope that the variety of subject indicates a rapid and remunerative demand for such transparencies.

Regarding the purposes to which these transparent enamel photographs can be, or are intended to be applied, it is unnecessary to enumerate. For almost every use to which painted or ornamented glass can be applied, we apprehend these photographs are equally applicable, and will, we conceive largely increase the use of pictorial transparencies for decorative purposes. Some elegant specimens of the application of these transparencies on white enamel glass, to lamp shades, were amongst the objects exhibited, and from what we learn, Messrs. Claudet and Houghton, who have undertaken their manufacture commercially, have already a good demand for them. The permanency of the pictures, and the possibility of subjecting them to all treatment to which glass may be properly subjected, are, we believe, undoubted. We congratulate M. Joubert, on the rapid and successful progress he has made, and on so speedily having brought his process to a state of perfection, which appears to warrant a hope that it will steadily take its place amongst the regularly practised arts with a fair share of commercial success.

EBONITE FOR PHOTOGRAPHIC VESSELS.

We have recently had our attention called to a new preparation of india-rubber, called Ebonite, which seems to possess all the peculiar characteristics necessary in vessels for photographic purposes. It is light, rigid, tough; it is not liable to breakage, it is not acted on by alkalies, nor by the various salts used by photographers; it resists all but the most concentrated mineral acids, and it is not affected by a temperature as high as that of boiling water. It appears to possess the hardness of ivory, without its weight or frangibility; and is just as capable of being turned and polished. Its applicability to various purposes of use and ornament appears almost without limit, but it is to its especial application to the purposes of the photographer we now direct attention. After its mechanical suitability, which is undoubted, the next important consideration is, how far it is acted on by a solution of nitrate of silver. On that point we think the report is most satisfactory. In the first place it comes under our attention with excellent credentials. We have seen a letter from Mr. Hockin, photographic chemist, in which he describes the various tests which, by the desire of Messrs. Silver and Co., he submitted vessels made of the material. A nitrate bath was placed in one of the vessels and maintained at a boiling heat for an hour and a half. It was then again cooled, and a collodion plate excited in the solution. The resulting picture showed that no change, whatever, had taken place in the photographic capacity of the bath. This was a severe test, and a tolerably conclusive one. In our own experiments, we have simply subjected the vessels to the same treatment as they will meet with in the ordinary practice of photographers. After satisfying ourselves that the material was innocuous, we made up a new bath consisting of about seventy ounces of solution, containing five ounces of nitrate of silver. This was slightly acidified with acetic acid, being intended for dry plates, and has now stood in the ebonite bath for a few weeks. We have, from time to time, since tried a plate, without finding the slightest deterioration in its qualities, the pictures being clean, rapid, and brilliant. Had we not been satisfied in the first instance, we should not have risked the spoiling of seventy ounces of silver solution.

Ebonite is an improvement upon a form of india-rubber, which has been some time before the public as vulcanite. This material has been found unsuitable for photographic purposes, from the presence of sulphur. In the preparation of ebonite, sulphur is, we understand, used; but the bulk of it is again eliminated in after processes; not more than two per cent., at most, remaining, and that so completely insulated as to be innocuous. Baths, dippers, and trays, are already made of this material, and it is possible that it may be found useful for other articles in photography: it has been proposed to substitute it for brass in the mounting of lenses. Those of our readers interested in electrical or galvanic experiments will find this material invaluable. As an insulator it is unsurpassed, and is the best material for battery cells which we have seen.

As our readers are aware we have always maintained that pure gutta percha was without action on nitrate of silver; its liability to adulteration, and the consequent uncertainty have been therefore the great draw-back to its use. In the case of ebonite, we believe there will be immunity from this danger, as the material, unlike gutta-percha, cannot be worked after it leaves the manufacturers' hands. After once undergoing the treatment which confers on it its peculiar qualities, it cannot again be made plastic. At present, therefore, there is no probability of spurious or adulterated forms of the material coming before the public, its manufacture being confined to the inventors, Messrs. Silver & Co., whose own interest in the matter, as well as their position, will preclude any fear of an inferior article being sent out.

PHOTOGRAPHY AND THE EXHIBITION.

The *Daily Telegraph*, in one of its able and interesting articles on the progress of the Exhibition and its arrangements, has the following:—

"By a hasty and ill-contrived arrangement, the blame of which rests pretty equally between the official authorities and the particular class of exhibitors interested in the question, photography will stand in a very exceptional and disadvantageous position in the industrial display of 1862. The original purpose of the commissioners was to class this new art with machinery. An outcry amongst its followers was raised with such effect as to procure an amendment of the plan, or rather a withdrawal of the obnoxious classification. A separate department was promised for photography. Meanwhile, the great mass of English photographers had, by their parent society, declined to appoint a committee; and, allowing their first feeling of mortification to influence their conduct for too long a time, they lost ground which may never be recovered. The appointment of Mr. P. Le Neve Foster to the superintendence of class 14, is accepted on all hands as a beneficial step; but photographers are now beginning to discern the importance of having a reliable body of gentlemen to represent so large an interest as they have in the International Exhibition of 1862. One of the most influential sections of the great modern guild, the South London Photographic Society, has memorialised the Commissioners on the subject, explaining their motives for desiring to be thus represented. We think their request, late as it comes, a fair one. Unless more decided steps are taken than have yet been indicated, British photography will not hold a very creditable position by the side of such a display as we have reason to expect from France, from Belgium, from Austria, and from all parts of Germany. It is a consideration, further, to be taken into account, that the practice of photography has received governmental aid abroad, and has been fostered to an extent not aimed at in this country. When we see those grand architectural pictures by the Brothers Bisson, we may be sure that accurate representations on so large a scale are not achieved without the aid of a costly apparatus. Indeed, it is a known fact that such a lens as that employed to photograph Rouen Cathedral and the porch of Notre Dame, costs from five hundred to a thousand pounds, or even more. To enable photographers to meet these vast expenses, so far beyond their ordinary means, the French Government comes forward with liberal grants of money. It is hardly necessary to say that State assistance in such matters does not accord with English notions. But this is all the more reason for extraordinary efforts to cope with the favoured art of other nations.'

In some of the above remarks our contemporary is a little inexact. A committee, as we have stated, is in course of formation, who will co-operate with Mr. Peter Le Neve Foster, to whom is intrusted the superintendence of the department: so far as there is any intention at present, therefore, photographers have no reason to fear that their productions will be handed over to the sappers and miners, as has been suggested. Mr. Foster is now at Florence, visiting the Italian Exhibition; and as photographs form an important feature there, some valuable suggestions as to arrangements will doubtless be gained. Regarding the remark as to the immense cost of such a lens as that used by Messrs. Bisson in their architectural work, our readers will at once see there is some misconception. Even were it true, English photographers desire no governmental subsidies: they simply require fair play; "a clear stage and no favour." There is no doubt whatever, but each nation exhibiting will excel in its speciality. But until there is proof to the contrary, we are unwilling to believe that this country will occupy the least distinguished position in the coming competition.

Scientific Gossip.

We have already drawn attention to the dangerous impurities existing in some of the pumps from which the poorer (and in many cases those well off) inhabitants of the city, draw their daily supply of this necessary. Dr. Letheby has just completed analyses of several more of the well waters, and with almost uniform results; in only two instances do they furnish water fit for human consumption. It behoves our city artists to keep these facts prominently before their minds, for all experience shows that the organic and mineral impurities present in water, are even more injurious to a photograph than to its living representative, although their effects upon the latter are sometimes very serious. Indeed, it may happen at any moment that a city well may become the receptacle for the leakings of a cesspool, or a sewer, and in that case it would be almost as dangerous for the photographer to take a draught of his cyanide of potassium solution, as a glass of the cool, bright, and sparkling beverage supplied by the treacherous pump. Several terrible instances, to corroborate this, are given by Dr. Letheby. In the autumn of 1854, there was a sudden and serious outbreak of cholera in the parish of St. James's, Westminster. The course of the disease was confined to a small area in the neighbourhood of a favourite pump, in Broad Street; and soon it was remarked that of seventy-three persons who died during the first days of the visitation, sixty-one had been drinking the water of the pump. It was also remarked, that among persons who were living in the same street, and occasionally in the same houses, those only were attacked who drank the favourite water of the pump; and, furthermore, in a number of cases which were particularly investigated, it was ascertained that persons who lived at a distance from the parish, and who had the water sent to them because of its supposed goodness, were seized with cholera, and died. A full enquiry into all the circumstances of the matter proved that the well had become charged with cesspool drainage, and had thus acquired its poisonous action. The pollution had perhaps been going on for years, and yet the water had not betrayed it, and had been drunk with comparative impunity; indeed, its cool and sparkling qualities, the fatal fascinations of corruption, had gained for it such a high repute in the neighbourhood, that it was a favourite water, and was generally drunk. Many similar illustrations are given by Dr. Letheby, to prove the danger of continuing to employ these waters, which, contaminated as they are with the refuse of drains, and the soakings of grave-yards, are unfit for public use. The pumps should instantly be removed, and their places supplied with drinking-fountains.

Chemistry has just conferred a great boon upon the artistic photographer, in the form of a rich and brilliant yellow pigment, which is possessed of all those qualities which are considered necessary to form a perfect colour. The new colour is termed aureolin, it is a chemical compound of as definite a character as nitrate of silver, and is of interest to the scientific man, equally with the artist, on account of the remarkable combination of good qualities which it presents. It is the nearest known approach to an elementary yellow, resembling the pure tint of the solar spectrum, nearer than any other known colour. Its tints, especially the lighter ones, are extremely delicate and clear; it combines with other colours in a very perfect manner, forming with blues a magnificent range of brilliant greens. With ultramarine, and madder red, aureolin completes a triad of *brilliant*, *permanent*, and *transparent* primitive colours, as it possesses these invaluable qualities in a very eminent degree. It has an advantage over all other yellows in its tints, being of wondrous delicacy and beauty without any intermixture of other colours; yellows generally bordering on a buff or orange tone, or on a greenish tinge, or they degenerate into various shades of brown. The transparent yellows, in addition to these defects, are generally very fugitive, and the permanent ones are opaque. But aureolin possesses other claims upon the notice of artists. It is absolutely indestructible and unalterable by any atmospheric agency. Several of our first chemists have experimented upon it with a view to ascertain its behaviour with chemical tests, and they report (and in this we can corroborate them) that aureolin is unchanged by sulphuretted hydrogen, or any gaseous impurities which ever find their way into the atmosphere. Long continued action of light has likewise no fading influence upon it, as samples have been exposed to the direct rays of the sun during the whole of one of our late intensely hot summers, without the least injury to, or diminution of, its delicacy of tint. Neither is it affected by, nor does it affect, any pigments with which it may be mixed.

At the last meeting of the Chemical Society some interesting facts connected with the metallic impurities present in commercial copper were communicated by Messrs. Abel and Field. This metal is frequently contaminated with arsenic, antimony, iron, tin, bismuth, silver and lead, but the usual methods of separating these impurities are very untrustworthy. Several details were given of improved analytical methods whereby the hundredth part of a grain of arsenic, or antimony could be detected in the presence of a hundred grains of copper. These results are very important, for chemistry is daily discovering that elements hitherto considered rare or sparingly diffused are to be found plentifully, if only proper search be made for them. Of these elements arsenic is one which is most frequently met with in the ordinary chemicals; and it is of the utmost importance to toxicologists that they should be in possession of ready methods of ascertaining whether their copper is contaminated or not with the very metal for which they are searching. It is now generally believed that some, at least, of the older discoveries of arsenic in supposed cases of poisoning were derived from the very impurity present in the chemicals employed in the research.

It is customary with druggists, and also with some unscien tific photographers to employ blue glass bottles for the purpose of counteracting the effects of light upon chemical and organic substances. In reference to this custom M. Dumey has recently called attention to the fact that such glass has no action on the chemical rays, and that blue glass is no better than white glass for that purpose. But excellent results are obtained when *red* glass is employed, as the most easily affected substances undergo no change from the action of light when kept in red glass bottles. We have long used yellow glass bottles for this purpose, but have experienced some difficulty in obtaining them of that particular shade which is necessary for the complete obstruction of all the chemically acting rays. Our researches in this direction with the spectroscope have shown us that this difficulty does not exist with respect to red glass, and that there is no difficulty whatever in obtaining in this material a perfectly *adiactinic* medium. From observations in our laboratory we are of opinion that not only should the more decidedly sensitive agents be preserved in bottles of this kind, but that benefit would be derived by enclosing every chemical used in photography in red glass bottles. Whilst speaking of bottles for laboratory use, our readers may be pleased to hear of a very simple contrivance which has lately been brought before our notice for the purpose of preventing the adhesion of the stoppers of bottles containing caustic solutions and other chemicals, which act upon glass after long-continued contact. Sometimes grease is employed for this purpose, but owing to the chemical properties of this substance it is soon attacked and rendered worthless by the caustic liquid, and, moreover, this latter is injured by the introduction of fatty acids. Now, paraffin in the solid state has been proposed as a very perfect lubricant for the contact surfaces of the glass, as, owing to its chemical passivity, neither caustic alkali, nor most other substances, act upon it.

A specimen of glass from F. L. cuts off all the blue and a great part of the green rays. It may be used with perfect safety except when strong sunlight is on the window, and a bromo-iodized collodion is used.

PRINTING-IN SEPARATE SKIES.

BY F. MAXWELL LYTE, F.C.S.

SIR,—The following letter was written in refutation of a critique on my pictures, lately exhibited at Brussels, and which I can hardly allow to pass unnoticed, as notwithstanding the flattering testimony which the writer bears to the artistic feeling displayed in them, the fault of which I stand accused would show that I was really not an artist at heart, and totally ignorant of the laws of composition.

It is stated that my pictures, though possessing much artistic excellence, are entirely devoid of harmony of purpose, or unity of effect, and that all this arises from my system of printing, by stopping out skies, and the introduction of clouds by means of a separate negative; the result being a hard outline on the horizon, and incongruity of effect. On the other hand, it is considered that the introduction of the same sky into several different views is wrong, and cannot but be fraught with disastrous effects, as exemplified in my pictures. Now, as the same pictures have been exhibited this year in London, Edinburgh, Paris, and Brussels, many of your readers will have had the opportunity of judging for themselves as to their merits.

I do not insert this note in defence of my own particular works, but in defence of the general system I adopt, which I believe I was one of the first to put into practice, having employed it in my pictures ever since the year 1853. I propose then to deal with the two points above mentioned, *seriatim*.

It is stated, first, that my pictures exemplify the fact that made skies (*ciels rapportés*), can never produce an artistic effect, and are always inferior to those naturally produced in a negative.

That my skies are many, indeed most of them, printed from a separate negative, is quite true, as may be gathered from a paper on photographic printing written by me, read before the Photographic Society of Scotland in the beginning of this year, and published in your columns.

So far then we agree to differ; but in order to understand whether the natural sky of a good negative is better, or worse, than one printed in afterwards, we must consider the nature of a collodion picture.

When a sensitive collodion plate is exposed to the light, and subsequently developed, it will, if the exposure has been sufficiently short, or the light sufficiently weak, present a dense black surface, almost absolutely impermeable to light; but should the exposure have been very prolonged, or the illumination too strong, solarization, as it is called, takes place, and the developed film takes a reddish violet tone after being fixed, and remains more or less permeable to actinic rays. Now in the production of a negative collodion picture of a landscape in the camera obscura, the sky, which is by far the most actinic and brightest portion, becomes almost invariably solarized before the exposure has been enough prolonged to reproduce the details in the deep shadows. The consequence is, that an operator's choice lies between two things, viz., the solarization of his sky, or the necessity of intensifying his picture by repeated doses of nitrate of silver added to the developer, producing what is technically known in the art as "*soot and whitewash*." It is true that by a cautious addition of bromide, and the use of salts of sodium in the collodion, by care and patience in the development, and by careful adjustment of the nitrate bath, solarization may be somewhat got rid of, but in a general way it always becomes necessary to solarize the sky before we can obtain a harmonious landscape.

A solarized sky is transparent, and prints dark.

Anyone who has studied nature, especially in mountainous countries, will have observed that the blue vault of heaven gradually fades to a paler hue as it approaches the horizon, except where some giant peak rears its head into the sky, and there the outline appears cut out sharply on the dark blue, whereas on the ordinary horizon, and especially at the end of the valleys, a whiter hue prevails.

This is what I try to obtain in my pictures as general effect, varying it from time to time to suit particular occasions.

And now we come to the second point, viz., that I have used the same sky for several different views, taken at separate times and places. I allow this to be the case, but refute what the writer says as to its disastrous effects, and will explain the reason of the apparent anomaly.

The valleys of the Pyrenees, with but few exceptions, run from north to south, and are consequently only lighted obliquely morning and evening. This oblique lighting is necessary to produce real artistic effects, with lights and shades, and to give real value to the different planes of distance. In the morning the air is almost invariably still during fine weather, but during the day the sun rarifies the air in the valleys, which, consequently, ascends and draws a draught of air up from the north, which reaches up the valley as it would up a chimney. This northerly breeze blows all day, and ceases again at night, with astonishing regularity, and generally finishes by driving up moist air from the plain, which condenses on the mountain, and produces cloud towards the afternoon and evening. Again the heat of the sun usually appears during the day to raise vapours, which although they may not even condense to cloud, interpose a sort of blue veil of mist, of a most anti-photographic nature, between us and the mountains.

Knowing these obstacles to exist, I always make it a point to be on my ground, if possible, and at work at an early hour, and more than nine-tenths of my pictures are consequently done by morning light, between the hours of five and eight, and the others are done, with scarcely any exception, by evening light. I have various negatives of clouds, taken in various positions of the sun, and it so happens that one of these is especially suited to the position of the light during the time at which I ordinarily work. This sky has, therefore, appeared on several different pictures, but never, I hope, with that incongruity of effect for which the writer of the critique gives me credit.

As to the sharp outline of the mountains against the sky, the writer should come down to the Pyrenees, and he will find that effect to be most frequent in our clear atmosphere, and on re-examining my pictures, he will see that I have been peculiarly careful in their treatment to convey the effect of distance, by the different tones given in the several planes, those at the extreme distance almost blending with the sky, and the nearer and taller mountains cutting out hard and vigorous. At the same time I have aimed at the production of a shaded sky, to blend in with the rest of the landscape, rather than a hard white one, or the dull monotonous discolouration, and the want of effect which would result from the printing-in of a plain solarized sky. Lastly, I may observe, that with the light coming from behind, even if the direction in which it falls be oblique, the clouds which can come within the range of the camera, can rarely, if ever, affect the lights and shades of a landscape, so that if the position in which the light falls on a cloud, harmonizes with the direction in which it strikes the landscape, the printing-in of a separate negative of such clouds can produce no incongruous effect This is just the position of light most favourable to the production of a good photographic picture, and the one, which as I have already explained, I, of necessity, almost invariably employ.

Bagnères de Bigorre, Nov. 4, 1861.

[The criticism which gives rise to these general remarks appeared recently in an able French contemporary, the *Moniteur de la Photographie.* The critic has fallen into a very common error, thinking the *use* of a principle or practice must be bad because it is possible to *abuse* it. Our readers know our opinion on this subject; we repeat it—success is the test of legitimacy. Those who remember Mr. Lyte's magnificent pictures in the last Exhibition of the Photographic Society in London, will be in a position to judge of his success. So far as our memory serves us at the present moment, it was complete; we do not remember one picture which was not exceedingly fine in harmonious atmospheric effect.—Ed. Photo. News.]

PHOTOGRAPHY AND ITS STUDENTS.

BY SAMUEL FRY.

With the large field opened by photography, both for amateur amusement and commercial enterprise, it would only be a reasonable anticipation that one would find a large variety of men and minds devoted to it.

Photographers as a body are loquacious, some have said gossiping; but I think the former word preferable; for certainly, if they do a good deal in the talking way, it is seldom without a good end in view; and how, if these matters were not well discussed, could any conclusion be arrived at? But in the mere talking part, what different characters do we come across; the unfortunate, unlucky, fellow who declares he mixed his bath according to Cocker, and his developer too, and yet he *can't* get a picture: certainly on cross-examination it turns out that he filtered it through a tin funnel, and used a filter paper through which his developer had just been passed, but surely these cannot cause any derangement!

Then another, who is "afflicted with an experimental turn of mind"—he has always a new process, but never any pictures; a little longer exposure, and it would have been perfect. "How truly unfortunate!" I hear him exclaim, "here's the finest film of the whole lot has slipped off the plate into the sink during development." Of course, it was the finest; did any one ever know an accident happen to any *but* the finest?

But there are two large classes with whom we can always meet; the first thinks his own pictures, and his own cameras, &c. &c., the very finest that can be; the other thinks *his* pictures, and *his* cameras, &c. &c., the very worst that can be got. "What a lens this is!" exclaims the first, "it really wants no focussing; I can see distinctly the signboard of the 'Cow and Snuffers' through it half-a-mile off; and then there's dry plates—certainly they want twenty minutes' exposure, but that's nothing; I don't prepare them myself, and when I've exposed, I send them to ——, to be developed, and then he sends them to Blackfinger & Co., to be printed. Now, that's what I call pleasant photography; no baths, no developer, no dangerous cyanide, nor anything else, including loss of temper."

But what of No. 2? He is a patient, zealous, enthusiastic worker, and though his results are often very creditable, he looks with a gloomy eye on everything, rarely satisfying himself; to his eye everyone beats him, his lenses are always bad, something or other's wrong; but it never strikes him that he himself may be wrong. Now there is another point that photographers are at issue about, and that is the expense necessary to go to, to obtain good pictures; it is certainly worthy of remark that results are frequently in an inverse ratio to the amount of money spent. During the present summer, being on the Continent for professional purposes, I received an introduction to a wealthy English amateur, residing in a lovely chateau; the house, the gardens, the stables, all bore testimony to the wealth and expenditure of the proprietor, if not to his taste. In reply to my first remark about photography, he exclaimed, "Ah, sir, I've done some wonderful things; already I can produce three primary colours in the same picture, and decided traces of a fourth." My curiosity was raised, the News should soon know all about it. Had he a specimen? Really at the present moment he had not, the discovery was so very recent, and he must perfect it. Would I like to see his glass-room, &c.; of course I would, I came on purpose. Arrived there, I found a large glass-room, cameras, and lenses by every known maker, collodion, bottles, baths, head-rests, tables, chairs, pilasters, backgrounds, &c. &c., enough to stock a large house of business; but I saw no negative except such as I concluded were wasters; my host being called away for a moment, his little son came running to show me the album of photographs, adding archly, "My pa, did every one of them." Horrors! could it be possible that these execrable productions were the work of those splendid lenses and cameras! had the fertile brain that could soar to the altitude of producing four colours in one picture produced these! It had, indeed, and worse; here was a case in which the royal road to photography was taken, and value thereof exhibited in the picture obtained. But now let us look for a moment in another direction.

A fortnight ago I received by post a parcel of very sweet, excellent photographs, about 6 inches by 4, which, a letter informed me, were the work of a shoemaker in a northern town, to whom I gave some instruction three or four years since.

Probably all his apparatus and stock are not worth more than £4 or £5; his only time for working before breakfast, or late at night, but he had studied the works of good photographers, compared them with his own, laboured until he came near the standard aimed at, and, to use his own words, having found a good process stuck to it; and though a careful reader of the writings and works of good photographers, kept steadily on, unless he saw good reason to change his ordinary practice. Now, really, these two men are to be found daily amongst photographers, and the ends obtained by each are well worthy the attention of all of us.

(*To be continued.*)

INSTANTANEOUS PHOTOGRAPHY.

BY L'ABBE' DESPRATS.

The results hitherto obtained in instantaneous photography, however marvellous they may appear at first sight, really present nothing very astonishing. We ought rather, it seems to me, to be astonished at arriving at these results so tardily. We are certainly far from wishing to depreciate the real merit which necessarily attaches to these new productions, but we believe there is nothing in them above the known resources of photography. Let us then briefly examine what these resources are, and perhaps we may discover that if, under the relation to instantancity, these resources seemed to have failed in the hands of most operators, it is owing to their not having availed themselves of them, and employed them simultaneously.

In what conditions, therefore, must we place ourselves in order to be able to operate instantaneously?

Above all things, we must be provided with a good collodion. No other photographic agent can be advantageously substituted for it. But as all photographers well know, there are very quick acting collodions, and also very slow ones. It is remarkable that ether in excess, although it yields a very tenacious collodion, causes it also to lose in sensitiveness. With alcohol in excess, just the contrary is the result. In excess of alcohol, the collodion is perhaps less tenacious, but usually more sensitive. This increase in sensitiveness appears to result naturally from a greater permeability, and consequently there are fewer obstacles to the action of light, and especially to the action of the sensitizing and developing solutions. It is true that collodions prepared with excess of alcohol are more quickly altered by time, particularly if the alcohol is too hydrated, but this is a very slight inconvenience, which will always be very largely compensated for by the importance of the result we have in view.

A second condition, and one of no less importance, is that of having a good light. Is it sufficient for that end to operate simply in the full sunlight? Certainly not. For unquestionably there occur days during the summer months, during which the atmosphere, although perfectly free from clouds, will nevertheless be much less luminous than if clouds occupied a considerable portion of it. Thus, a landscape may be very luminous, especially if to the direct light of the sun it receives, there be added much light reflected from strongly illuminated white clouds. These two conditions do not always present themselves, but as they do occur occasionally, the operator must avail himself of them. But still this is not all. Not only must he seek a good light, but he must also economise it as much as possible: that is, his camera must be fitted with two objectives of large diameter and short focus.

It may be readily understood that diaphragms, however large, cannot be employed in this case, for the loss of light would be considerable, and put an end to instantaneity. But then it may be asked, what will become of sharpness? It will be such as we see in certain instantaneous proofs of commerce, rather imperfect it is true, but still passable. It is only with a first-class objective that we can attain instantaneity, in limiting ourselves to employing known means. It must be clearly understood that in this place we speak only of stereoscopic pictures; the dimensions of which are sufficiently limited to admit of the objective covering the whole area with the desired degree of sharpness.

It is of course understood that the two objectives of the stereoscopic camera must act simultaneously upon the same plate, and have the same focus, obtained by working a single screw. The caps must be made to open and shut without the slightest intermission. This is the business of the optician, and presents no difficulty.

There is a third condition, less important, less decisive perhaps than the first two; but which, nevertheless, must not be neglected. This is the sensitizing bath. All baths are not equally sensitive. Neutral baths, a little old in use, are much better than acid baths. We insert, in the first place, a very pure nitrate of silver, well crystallized in perfect crystals. In this state it is not acid; but it is easily rendered acid by fusion. This fusion must be performed by the operator himself in a porcelain capsule, placed on slightly incandescent charcoal. The operation must not be considered as complete until the salt has become quite fluid, and the black reductions obscure the whole mass. In brief, the action of the fire may be pushed just so far as to obtain a disengagement of red fumes due to deutoxide of nitrogen. The bath prepared with such a nitrate, will sometimes cause a slight general fogging; but as this veil is uniform, it will injure the sharpness of the negative, only the positive will print a little slower, which need not be considered as a serious defect. It has been stated above, that a special bath will greatly promote instantancity; but there is no occasion to repeat in this place what must be well known to all photographers. As may be seen, it is only necessary to make them all concur to the same end. Unfortunately, at the present season, the sun is not very liberal of its beams, and we are thereby deprived of one of the three conditions laid down as essential to success in instantaneous photography; but with the return of summer, we are sure that disciples in this branch of the art, recognizing upon what success depends, will greatly increase, and the number of their admirers also.

GLASS POSITIVES IN GOLD.

Mr. W. J. Miers, writing to our contemporary, the *British Journal*, suggests a method whereby the silver forming the image in a collodion positive may be removed, and gold substituted in its place: the process having especial view to ornamental purposes. He says:—

"The method of proceeding I adopted was this:—Taking a positive or negative with clear lights, the surface was first wetted, and then flushed over with a solution of chloride of gold, of a light sherry colour, several times, until the maximum intensity was obtained; the plate was then thoroughly washed, slightly drained, and then immersed in dilute nitric acid (about acid one, water two parts), or the acid may be poured on, as in developing, for one or two minutes.

"The plate is to be rinsed, then drained for a few seconds, and a strong solution of ammonia poured over it for about half-a-minute; the plate is to be again rinsed and the nitric acid applied, also the ammonia, taking care to rinse between the operations, which, if repeated three or four times, will clear the plate of any visible traces of the silver picture; nor will the picture when viewed by transmitted light, now present any indication that the silver forming the picture at the commencement of operations has been dissolved away—yet in the subsequent stage of the process the lightest shades of the positive are found to be reproduced in another material. The plate is then to be dried carefully and subjected to some operation for reducing the black, precipitated gold to its proper colour."

The steps for reducing the gold to its metallic form Mr. Miers was prevented by other engagements from carrying fully out; but he makes the following suggestions on the subject for the guidance of those who may have opportunity of prosecuting the enquiry:—

"There are many ways of effecting this reduction, as phosphorus in the presence of aqueous vapour, sulphurous acid, &c.; but the readiest was putting the glass in a kind of muffle in a common stove, making it red hot, for a few minutes, and withdrawing it very gradually to prevent the glass from cracking. The necessary apparatus can be readily made by taking a piece of iron, about the thickness of half-a-crown, rather larger than the glass, spreading upon it some whiting about 1-16th or 1-8th of an inch deep, the surface of which is to be pressed quite flat and level with a piece of board or glass. The picture is then to be laid on the whiting, face upwards, another piece of thin iron slightly bent, so as not to touch the face of the picture, is to be placed on the top. This iron is to be rather wider at the side and bent so as to clip the under side of the thicker iron plate, forming a kind of cover open at both ends, through either of which the thicker iron and picture may be inserted or withdrawn. This may be placed on an ordinary fire, if burning clearly, and allowed to get red hot; and if withdrawn gradually and kept from draughts the glass will seldom crack. But in a great many of my experimental plates the glass was merely clipped by a piece of soft iron wire wound round it and held in the hollow space of a clear fire for a few seconds until red hot, not allowing the glass to lose its shape by keeping it too long in the fire.

"The precipitated gold forming the picture will now be found changed in colour from an ugly, dense, slaty, black, to its natural colour, approaching somewhat the well-known appearance of water gilt-work in ormolu; but the colour is not always pleasing, having at times a slight red tinge. As far as I can recollect, however, this depends on the strength of the gold solution, a weaker solution producing more favourable results. But as it is more than three years since I have experimented on the subject I am not quite certain on this point. I have very little doubt in my own mind that if this part of the process were more fully worked out, perhaps, by some of your numerous readers competent to undertake the task, some highly successful results would be obtained—perhaps the opening out of a new branch of practical photography in a useful and advantageous direction."

It is not for portraiture this process is recommended, as golden flesh, &c., would scarcely have a desirable effect. It is obvious, however, that in various branches of ornamental or decorative art, the results might be useful. Mr. Miers adds:—

"It is very easy to combine the two effects of gold and silver on the same surface by gilding first, using two negatives, one for each operation, arranging and blocking out the parts so as to avoid the interference of one process with the other, while with the further and appropriate addition of colour novel and pleasing effects might be produced unattainable by any other means.

"By way of caution I should recommend those who do not meet with success at first to try again, and to make their own chloride of gold, as that obtained at some places, and used for colouring paper positives, may not always suit for this purpose."

A field for ingenious experiment is here suggested, and if the ideas promulgated in Mr. Malone's paper in last week's Photographic News, relative to the production of variety of colour from the various modes of reducing the same metal, be borne in mind, some interesting results may be obtained.

PHOTOGRAPHY.

(*From The Mechanic's Magazine.*)

[In reprinting the following interesting article from our esteemed contemporary, the *Mechanic's Magazine*, we cannot forbear suggesting to our readers the contrast between the dignified and intelligent tone which distinguishes these remarks, and the swaggering sneers of the *Engineer*, recently noticed in our pages.—Editor Photographic News.]

The wondrously rapid development of scientific knowledge, and its practical application to the arts, useful and ornamental, during the first sixty years of the 19th century, go to make that period one of the most noteworthy in the history of the world. Two of the most remarkable instances of the growth and advancement of science, and of its reduction to successful practice are, unquestionably, the steam-engine and the electric telegraph, but photography is assuredly also one of the scientific marvels of the present age. To this latter we now propose to devote a little consideration and space, for "every day soft as it rolls along" reveals, in connection with photography, "some new charm." The Great Seal Office, that *alma mater* of inventors, furnishes the clearest and most satisfactory evidence of the activity of the votaries of the beautiful art, and from that prolific fountain we shall, accordingly, draw our facts for the elucidation of its history.

To the indefatigable and talented Mr. Bennet Woodcroft, the public are indebted for having rendered comparatively easy of accomplishment the task of obtaining information relative to any or all of the branches of art and of science which have taken root in Great Britain, not only during the present, but the *past* century, and even *its* predecessors. Mr. Woodcroft, by his admirable system of indexing and classifying the contents of the Patent Office, has indeed supplied the student and the inquirer with the clues, by aid of which they may thread easily that labyrinth of scientific knowledge, and return laden with such spoils of rich information as will well reward them for their journeyings.

In relation to the art of Photography, the gentleman in question has just rendered especial service to all who take an interest in it, and these may be said to comprise the entire population of the civilized earth. He has published, in the form of a small blue book of 165 pages, an "Abridgment of the Specifications relating to Photography." This work, which now lies before us, contains the pith of the various patents which have been from time to time taken out in regard to the art in question, with the dates and the names of the patentees. The compiler of the "Abridgment" very justly expresses, at the outset, and by way of preface, a hope "that the publication will prevent the disappointment consequent on re-patenting an old invention, and by setting forth what has been already done in this department of applied knowledge, cause inventors to exert their talents only upon discoveries and applications that are new." Undoubtedly this is an important consideration in the arrangement of abridgments of specifications, for the mortification and the expense of securing a patent which, after all, is invalid, have been frequently incurred, and are very great. There is, however, another point in favour of these classified hand-books of patented "discoveries and applications," and that is, the easy means they afford of tracing step by step the onward march of the applied sciences, and gauging, as it were, the amount of progress actually achieved in each department of them.

The definition of "Photography," as given by the compiler of the "Abridgment," is, that it is "the art of copying designs or images, however they may be produced, by the chemical action of light upon surfaces prepared to receive that light," and, perhaps, a more intelligible and comprehensive explanation of the term could scarcely be furnished, even if half a page of matter were devoted to the effort.

It will, of course, not be expected that we shall trace the development of Photography from its dawning to the present time, when it is apparently in the very noontide of its prosperous career. No less than 280 names of persons, English and foreign, who have assisted in developing the art of Photography, are mentioned in the manual, and the particular parts they played are specified with sufficient exactitude to show how much of public acknowledgment is due to each.

It is remarked, by Mr. Woodcroft, "That although the action of light on coloured bodies must have been of every-day occurrence, the philosophers of antiquity did not record the fact, and the chemical action of light upon matter would appear to have escaped their notice. The first definite knowledge of this action appears to have been some observations of the alchemists that 'horn silver' (chloride of silver) was blackened by exposure to light. Although the Middle Ages thus furnished one of the facts upon which the scientific principles of photography depends; the others, viz., the proper application of designs or images to sensitive surfaces, and the permanent fixing of the pictures so obtained, are belonging to the present era."

The chronological list of individuals who have remotely or recently thrown light upon matters related to photography, or who have made discoveries which have since been applied in any way to it, commence with the name of Euclid, 300 b.c., who, in his "Treatise on Optics," proves that he knew that "the pictures of bodies seen by both eyes are formed by the union of two dissimilar pictures formed by each eye." This discovery certainly entitles Euclid, in addition to his mathematical honours, to some fame in connection with our subject; for the stereoscope, that admirable adjunct to photography, is based upon the last named principle.

Prominently among the long list of inventors and others who have in modern times advanced the art of photography, are the names of William Henry Fox Talbot, Antoine Jean Francois Claudet, Richard Beard, John Edward Mayall, Paul Emile Chappuis, and others, whilst the last on the honourable catalogue is that of Arthur James Melhuish.

Probably we have said enough to show the nature of the book of which we speak, and to induce those who desire further knowledge of a chronological or historical character, to obtain it, and seek out that knowledge for themselves. It is needless, too, for us to urge the claims of photography as it stands before the world at present. From the Queen down to the humblest of her subjects, the art has admirers and patrons; and although some of its so-called professors have done their best to degrade it, yet it is likely that it will retain its popularity as long as the sun shines and "images" of the forms and faces of loved ones may be "produced by the chemical action of light upon surfaces prepared to receive them."

Of the innumerable practical uses to which photography has been already put, and of the new triumphs in store for it, much might be written, and much speculation based, but it is unnecessary. Next year there will be a vast stock-taking of the material, artistic, and general progress of the world, and the naves, aisles, and transepts of the Kensington Temple of Science will be rich in the display of objects of beauty and utility; but, perhaps, no part of the Great Exhibition will be regarded with more real interest than that set apart and consecrated to photographic works. In that department, there will, undoubtedly, be found reflexes distinguished by those minute points of resemblance, which only photography can produce, of all the remarkable people and places of the globe on which we live, While, therefore, in the various courts of the Great Exhibition there will be seen specimens of the workmanship of the inhabitants of each country, and specimens, also, of their natural products, to the photographic section the visitor may turn, and gaze on sun pictures, wrought with all possible fidelity, of the features of the various lands from which those specimens and products came.

Who shall gainsay, then, the fact that photography will play a great part in the coming festival of talent. It, indeed, and literally, "holds the mirror up to nature," whilst on that mirror nature indelibly paints her wondrous forms and features.

We are aware that an unseemly question has arisen between the Commissioners of the New Kensington Palace and the principal exponents of the art of Photography, as to the rank and position it shall take in the halls of that place. We certainly see no good reason for excluding Photography from the Fine Arts department, as there is ground for fearing it is the intention of the ruling powers of the International Exhibition to do. The Photographer, in the sense in which we understand the term, is as much entitled to be considered an artist as is the engraver or the painter, and the works he produces are as much works of art as theirs. In saying thus much, we have no wish to disparage the labours of the engraver or the painter; but rather to elevate the labours of the photographer. To form a perfect photograph, a great deal of delicate manipulation is required on the part of the operator, who also must understand completely the effects of light, shade and distance. Chemistry must have been mastered by him, at all events so far as it has any bearing upon the art he practises, if he is to be anything like successful in the practice of the latter. The effects of careful groupings and of colours must also be known to him, and more especially so in Photographic portraiture. In short, it seems to us that a gross injustice will be done to Photographic artists if, in the Exhibition of 1862, photography be not allowed to occupy the position which the voice of public opinion awards to it, namely, that of one of the Fine Arts.

ON THE PRACTICAL APPLICATION OF PHOTOGRAPHY TO THE MICROSCOPE.

BY PROFESSOR O. N. ROOD.*

Collodion.—This article when furnished by makers of repute can of course be used, though it is better for more than one reason to be independent of the dealers if possible. A considerable number of samples of pyroxyline were prepared according to different receipts, and sensitized variously. The very simple process described by Waldack, on page 266 of his *Treatise on Photography*, was found, with slight modifications, to yield an excellent article. The strength of the sulphuric acid was slightly greater than recommended by him; no water was added; the temperature also was slightly higher at the time of the immersion of the cotton. A more prolonged washing than that described in this work is desirable. This collodion can be sensitized with advantage by the iodide and bromide of cadmium, in proportion of four to one. A receipt published in *Humphrey's Photographic Journal* has lately been used by me with very good results.

No. 1.		No. 2.	
Plain collodion,	1 oz.	Plain collodion,	1 oz.
Iodide of ammonium,	5 grs.	Iodide of potassium,	5 grs.
Bromide of potassium,	3 grs.	Bromide of ammonium,	5 grs.

Dissolve the iodide of ammonium and bromide of ammonium in alcohol, the iodide of potassium and bromide of potassium in the least possible quantity of water, before adding them to the plain collodion. Mix Nos. 1 and 2 in equal parts for use.

This collodion, when used according to the wet process, though not very intense when first made, is quite sensitive, negatives of landscapes being obtained in $\frac{1}{4}$ of a second, indicating by their strength that a shorter time would suffice. It acquires intensity by keeping. The exposure is effected by the flap at F, and will last from $\frac{1}{2}$ of a second to four minutes according to circumstances. The development is as usual, hyposulphite of soda being used as a fixing agent. The use of the bromide of arsenic, mentioned in the same journal, gave with some samples of collodion excellent results so far as intensity was concerned.

The negatives thus obtained are examined by a lens of one inch focal length, to test their degree of sharpness. This quality will not only vary with the manipulation, but with the nature of the object: the sharpest negatives obtained by me, when examined by a power of 40 diameters, appear as well defined as finely executed lithographs seen by the naked eye, while other classes of objects (dots in pine wood, &c.), with all care, yield negatives which present the same appearance under a much lower magnifying power.

Positive Prints.—In order to preserve the fine details, the prints should be taken on glass, not on paper; mica answers when a print is to be transmitted by mail. Great care should be used that little or none of the fine markings on the negative are lost in this process; a bright light (sunlight thrown on the negative backed by ground-glass), a small diaphragm before the copying lens, and careful allowance for the chemical focus, are the essentials. To produce enlarged positive prints on glass, the negative is placed on the stage of the microscope, and treated like a microscopic object, the magnifying power varying from 5 to 20 diameters. If the prints are to be on *paper*, it will be found that a more liberal use of nitrate of silver and chloride of gold than is generally recommended, makes success easy.

Magnifying Powers employed.—To produce enlarged images, the objectives, as is well known, may be used alone or in connection with an eye-piece. In the former case, with proper illumination, sharp images are produced when the distance between the object (on the stage) and the ground-glass is as great as five feet. With this distance the

1 inch enlarges 65 diameters.
$\frac{1}{3}$ " " 190 "
$\frac{1}{7}$ " " 450 "

In using the objects in this way the screw collar is set *after* the microscope is connected with the camera.

For more highly enlarged images it is best to add the long eye-piece as has been practised by some experimenters. The adjustment of the screw collar can then be very nearly

* Continued from page 531.

completed before the microscope is connected with the camera, which is a great saving of time: it will, of course, fall nearer the mark "uncovered" than in the first case. However perfectly this operation may be performed in either instance, allowance must still be made for the actinic focus. By varying the distance between the eye-piece and the ground-glass, different degrees of enlargement are obtained. When the long, or two-inch eye-piece is used, the distance from the object-slide to the eye *lens* being 12 inches, from the latter to the ground-glass 34 inches, then

1 inch	enlarges	160	diameters.
$\frac{1}{3}$	,,	550	,,
$\frac{1}{7}$	,,	1300	,,

Powers obtained in this way with the two latter objectives have been used by me with advantage.

Thus with the 1-7th 113° aperture, the Wollaston doublet of 44° aperture, having a central stop, being used as a condenser, I obtained sharp negatives of the *P. angulatum* magnified 1300 diameters, with well defined hexagonal markings similar to those obtained by Wenham with a 1-12th of 130° aperture. Portions of the negative bore a photographic enlargement of 10 diameters. Mr. Wenham announces* that he has discovered, by the use of a 1-30th of large aperture, made by himself, that the markings on this object and on some others, are really due to spherical particles of quartz, which can be made by illumination to appear hexagonal. With a power too low, I obtained photographs of the *P. Balticum* with *hexagonal* markings; with a higher power and a larger angle of aperture, the tendency was to the spherical form.

Photographs by Polarised Light.—A Nicol's prism is placed under the stage, one also directly behind the objective, sunlight is reflected from the mirror, and one of the prisms revolved till the field is dark; with the low powers, by this simple arrangement, photographs of objects may be obtained which exhibit the structure revealed by the polarised light. For higher powers it is necessary to use the polarising arrangement described by Von Mohl, *Pogg*, vol. ciii. p. 178, and recommended by Carpenter; that is, the light from a large Nicol's prism is concentrated on the object by an achromatic condenser. The perfection with which this apparatus operates may be inferred, when I state that photographs of the cross and rings in starch granules, as well as of the *P. angulatum*, in a dark field, were obtained by me without difficulty. Von Mohl remarks that with inferior apparatus some very distinguished observers have been unable even to *see* these appearances. The selenite stage can of course be used when it is found desirable.

By arranging the apparatus according to the plan adopted by Prof. v. Kobell in his micro-stauroscope (this Journal [2], vol. xix. p. 425), the peculiar effects which microscopic crystals produce on the cross and rings of calc spar can be photographed. By removing the condenser and objective, as well as the slide containing the crystals, beautiful photographs can be obtained of the normal cross and rings; the systems of rings in other crystals can be photographed by substituting them in place of the calc spar, as well as the changes which they undergo by combination with plates of doubly refracting circumstances (circular analysis, &c.), it being merely necessary to introduce the plates or films at the proper positions. I was shown by Prof. Dove some years ago, while in Berlin, photographs of the normal cross and rings around the axis of the calc spar; but, so far as I know, this is the first attempt to photograph the changes which the cross and rings undergo by the action of microscopic crystals.

Stereoscopic Photographs of microscopic objects can be obtained with the monocular microscope, by covering first the right-half of the objective, then the left by a suitable brass cap, and taking two successive pictures. When using this method it becomes necessary to move the mirror towards the right or left hand with each successive exposure, which is not only inconvenient, but often produces a slight distortion that prevents the proper stereoscopic union of the two photographs. On this account I have generally adopted a different plan. The object is placed on an extra stage, which can be inclined from 5° to 10° as seen in profile in the woodcut, *fig.* 2: it is photographed first at one angle then at the other. In practice the manipulation is easy, and no particular difficulty is experienced from the fact that the extreme right and left hand portions of the field are thrown slightly out of focus. High and low powers can be used equally well. The second negative should be taken immediately after the first, before the illumination has altered. I do not know that stereographs of microscopic objects have actually been taken by other experimenters, though this may easily be the case.

Fig. 2.

Living Organisms offer the photographer some difficulties by their constant motion about the field, and in and out of the focus. It becomes necessary to adopt a plan by which the image can be thrown on the sensitive plate the very instant after the animalcule has been brought into focus. The following method has been used by me with success to obviate this particular difficulty:—A plate of glass with parallel sides is introduced at an angle of 45° into the tube outside of the camera: it reflects an image of the object to the ground-glass at G, *fig.* 3, which is placed so that an equally sharp image of the same object is formed at G′. The sensitive plate is introduced at G′, the flap at F being closed: with one hand the operator, by the aid of the image at G, focusses on the animalcule; just as this is effected, the plate is exposed by the other hand turning the flap. If the collodion be sensitive, a second, or less, suffices to give an image; if a longer exposure be desired, the image of the animalcule on the ground-glass at G can be watched, and the exposure prolonged till the creature begins to change its position. The real difficulty in the case of living organisms is found in the fact that all parts of them do not lie in the same focus. This in fact is one of the most important difficulties connected with the whole subject of microscopic photography; but the introduction of a slight modification in the ordinary *compressorium* removes it in many cases. The plate of glass on which the objects rest, instead of being plane, is made slightly *convex*, by the use of a spectacle lens of rather long focus. Objects to be examined are placed near the point of contact, and pressure applied as usual, when they are brought nearly into the same plane.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 13th November, 1861.

It is pleasant and gratifying to the earnest photographer to watch the upward growth of his favourite art, and trace its geographical process. It is not long ago since I announced the formation of a Photographic Society at Marseilles, which may be regarded as the second capital of France. So popular has the art of photography become, that already this Society numbers its 700 members, and has lately organized an exhibition, with the distribution of prizes, which has been most numerously attended. The secretary, M. Louis Vidal, had the tact to deliver three lectures on popular branches of the art, exhibiting the processes of carbon printing, of photo-lithography, of heliographic engraving, of heliochromy, of enlarging negatives and positives, and to describe the various apparatus employed in photography. These lectures were remarkably well attended, ladies forming a large portion of the audience, and there can be no doubt that the zeal and intelligence of the secretary will have the effect of popularizing photography among the people of our Southern Capital. I think some of your societies, which address themselves so exclusively to the practical photographer, professional or amateur, would do well to follow the example set by M. Vidal, and address themselves familiarly to the general public, a large accession of members and consequent increased power and usefulness would doubtless result.

M. Reynaud has invented an economical gunpowder applicable for mining purposes, to which he gives the name of *pyronome*. It consists of—

Nitrate of soda	52·5
Spent bark (tan)	27·5
Sulphur in powder	20·0
	100·0

Its preparation requires the following operations:—

1st. To dissolve the nitrate of soda in a sufficient quantity of water.

2nd. To mix the tan in this so that it becomes thoroughly impregnated with it.

3rd. To mix the sulphur in the same manner.

4th. To withdraw the product from the fire, and dry it.

5th. To complete the drying, and pack the compound in sacks or barrels.

Moistened and dried anew, the *pyronome* has not lost its explosive qualities, and may be employed as when first prepared. This valuable quality renders it superior to ordinary mining powder.

The Emperor Louis Napoleon, in recognition of the value of their discoveries in spectrum analysis, has given to Professor Bunsen the decoration of an officer, and to M. Kirchoff the cross of the Legion of Honour. M. Dumas wrote a very interesting communication to the *Moniteur* apropos of this acknowledgment of the learned Germans' services to science.

VARNISHES FOR NEGATIVES.

Dear Sir,—I generally make my own negative and positive varnish, but the other day being out of stock, was induced to use some of Gaudin's French varnish, and the consequence was that a portion of the collodion film was shifted and nearly floated off into the bottle. As an experiment, I added to the bottle of varnish ten drops of distilled water, shook it up and let it stand all night, tried it on a plate next day, and have used it since in perfect safety, with not the slightest symptom of the film shifting. Perhaps the above hint may be useful to others, as it has been to me.

To those who make their own varnish, the following method of bleaching shellac may be of service:—

White shellac.—Take two or three ounces of orange shellac, put it into a large evaporating dish, and melt it slowly over a clear fire; when melted pour it on a stone slab, or a piece of slate, let it set a little, then draw it out quickly, and throw it over an iron hook, double it up and throw it again and again, several times, till it loses its colour, or begins to set, and in that case warm it over again before the fire. It may be done by drawing out with the hands only, and doubling it up quickly, but throwing it over a hook or large iron nail is most effectual.—Yours truly, Thomas Gulliver.

Heathfield Street, Swansea.

[Shellac is unquestionably the best basis for a negative varnish. We have never recommended photographers to make their own varnishes, as the process is troublesome, and the result not always efficient. We regret to add, however, that we have received many and varied complaints recently of commercial photographic varnishes. Possibly in some cases the evils complained of may be overcome by the exercise of a little judgment and ingenuity, such as our correspondent describes in the first part of his letter. One correspondent recently describes the loss of some negatives through using Rigge's varnish, which stuck to the paper, and destroyed the film. It is always wise in using a new sample of varnish, to test it first, and learn to humour its peculiarities before risking its use on good negatives.—Ed.]

THE NATURE OF THE PHOTOGRAPHIC IMAGE.

Sir,—I have read with much pleasure the report which appeared in your journal last week of Mr. Malone's discourse at the London Photographic Society. In referring to the chemical nature of the photographic image, the lecturer had selected a topic particularly interesting to me, from the circumstance that it is one upon which I have been experimentally engaged; and it affords me much satisfaction to observe the close conformity between the views now advocated by Mr. Malone with those published by myself in the *Philosophical Magazine* for March, 1860. The analogy between the coloured products on our chloride of silver paper, and the red and purple gold of Professor Faraday, appeared to me to warrant the comparison mentioned in my paper; and with respect to the action of light upon chloride of silver, I am convinced that the state of aggregation of the particles of reduced metallic silver, and similar physical considerations, are competent to afford a correct scientific explanation of the wide differences in colour observed in these and other products chemically identical.

Having myself encouraged the hope that it would be possible to solve the question analytically, I took steps to prepare a sufficient quantity of a material which at the time was thought to represent the ultimate product of the action of light. For this purpose, solutions of rock salt and nitrate of silver, excessively dilute, were mixed and exposed all day to the scorching influence of a midsummer sun; the salt being employed in the proportion of less than a grain and a half dissolved in one gallon of distilled water. An opalescent liquid, without visible particles of white chloride. was the condition in which the substance was presented to the decomposing action of the sun's rays, and what was the result? The product had such a chemical composition—silver 82; chlorine 18 per cent. That it might be assumed that one-third of the total amount of white chloride submitted to its action was reduced to metal, the remaining two-thirds being so well incrusted and protected as to escape decomposition.

If this experiment were repeated under circumstances of even greater dilution, the product would contain a larger proportion of silver in admixture with the unaltered chloride; but until we have succeeded in passing the limit prescribed by the composition of the assumed subchloride, Ag_2Cl, the analytical determination will not be considered as furnishing any data for the correct interpretation of the chemical change.

By diligently collecting the products obtained from forty-six gallons of these excessively dilute solutions, I was placed in the possession of a sufficient quantity of "blackened chloride" to enable me to study its reactions, and perform the experiments described in the account referred to. Without proceeding to the enumeration of these, it may be sufficient to mention, that the weight of chemical evidence appeared to justify the conclusion, that metallic silver, and not the hypothetical subchloride, was the invariable product of the action of light upon white chloride of silver; and that certain physical difficulties operated in determining the partial nature of the reduction under ordinary circumstances. It remains, finally, to be mentioned, that these results do not entertain the question of modifications possibly introduced by the presence of organic matter.

From this statement it will be seen how truly corroborative of my experiments were the remarks lately made by Mr. Malone, in reference to the nature of the action of light upon our common photographic surfaces.

I am, sir, yours obediently,

John Spiller.

Chemical Department, Royal Arsenal, Woolwich, Nov. 12th, 1861.

COMMON WATER FOR THE SILVER BATH.

Dear Sir,—Your correspondent E. F. G. is really very considerate in writing to you so promptly, after his "first and last trial," to save others being "misled" by using my method of preventing the printing-bath discolouring. I have to thank you for stating in the foot-note, that you know the process succeeds in my hands; I also know it, but I should not expect it to succeed if I added acetic acid to the bath. Has E. F. G. any idea why *he* adds it? I imagine not; this is just a case in illustration of a very serious evil amongst photographers, where persons making a single crude experiment, and of course failing in the expected results, at once rush into print. Allow me to inform E. F. G. that I never use kaolin, and never filter my bath, and it is invariably clear as a glass of spring water. I will once more describe it, and trust that others will find it the boon I do, and thus save 15 or 20 per cent. of silver.

I dissolve the silver, 70 or 80 grains to the ounce, in water drawn from a tap of the ordinary London water supply, which produces a dense white cloud of carbonate of silver, and probably other insoluble salts of silver. In a few hours this has settled down, and carried with it any floating matters the water may contain in suspension; I do not filter it out into the dish, for the simple reason that there is nothing to be extracted. When done with, I pour it back, and shake up the bottle; once again the carbonic sediment pervades the fluid, and then as before clears down all colouring matter, and floating particles. I have used this commercially, for at least two years, and strongly recommend it.

Samuel Fry.

West Kent Park, Nov. 11, 1861.

[We scarcely agree with Mr. Fry that it is an evil for photographers to state the result of their experience. Experiments should always be conducted carefully; but it is only by the interchange of experience that progress is made.—Ed.]

ROYAL REWARDS TO PHOTOGRAPHERS.

Humphrey's Journal says:—"We notice that Messrs. Gurney, of Broadway, have received by a late steamer a full acknowledgment of their attention to His Royal Highness the Prince of Wales. It seems that they sent to the Prince an elegant photographic album containing portraits of himself and suite. The acknowledgment comes in the shape of a large gold medal, with the Prince's head on one side, surrounded by the words, 'Albert Edward, Prince of Wales,' and his crest, the plume, and motto, on the other. Around the edge of the medal, which is about three-eighths of an inch thick, are the words, 'Presented to Messrs. Gurney and Son, Photographers, New York, 1860.' Accompanying the medal are letters of thanks from Major-General Bruce, on behalf of the Prince. Messrs. Gurney have received similar letters from the Duke of Newcastle, on behalf of the Queen, and from the other members of the Prince's suite, acknowledging the elegant portraits he has sent them.

"The following is a copy of the letter received in acknowment of the portraits sent to the Queen:—

"*Downing Street, London, Feb.* 26, 1861.

"Gentlemen,—The Queen has received the album and oil portrait of the Prince of Wales.

"I am commanded by Her Majesty to convey to you her thanks for these beautiful specimens of American art, and to assure you of her appreciation of the skill with which they are executed, and of the feeling which prompted you to send so interesting a *souvenir* of the visit of His Royal Highness to New York.—I am, gentlemen, your obedient servant, Newcastle.

"*Messrs. Gurney and Son.*

"Prince Alfred is now in Canada, and will be in New York shortly; then there will be a chance for more albums and more medals. Who is to be the happy man? We think it is Fredricks' turn now, as he has got the handsomest gallery."

Photographic Notes and Queries.

Discolouring of the Silver Bath.

Sir,—I noticed in last Friday's News a letter from D. H. F., which induces me to send you the following.

I make my printing bath with distilled water having 80 grs. of nitrate of silver to the ounce, but a small proportion of the positive collodion bath (after adding nitrate of silver to the required strength) had been mixed with it. I have always used kaolin for decolorizing till about last March, when working with a different sample of Rive paper I found my bath did not discolour. The next sample—obtained from another house—made the bath discolour, I then purchased some more of the Rive paper above-mentioned, since which time my bath has never discoloured. There is a small amount of black sediment, which of course is disturbed in pouring back into the bottle, but in a few hours, it is again clear and ready for use. I never filter it. I obtain my paper from Mander, of Birmingham.—I am, sir, yours respectfully, J. W. Fall.

White Fire for the Photogen.

Sir,—Seeing in your "Answers to Correspondents" of last week, one to N. X. concerning "white fire," allow me to mention one that is very bright indeed. It is

Nitrate of potassa	... 4 parts
Sulphuret of antimony	... 2 ,,
Sulphur	... 1 ,,

Powder and mix well.

I remain, your obedient servant, J. L. Davies.

Clapton.

Sir,—Seeing in last weeks News that your correspondent N. X. wishes for information respecting the composition of Moule's Photogenic Light. I beg to inform him that in Dr. Muspratt's chemistry, it is stated to be composed of

Pure saltpetre (nitrate of potassa)	... 112 parts
Flowers of sulphur	... 42 ,,
Black antimony, (sulphide) ...	... 12 ,,

Yours respectfully, W. Burnell.

Splitting of the Film.

Dear Sir,—I should feel greatly obliged if you could suggest a remedy for the splitting up of the film of a dry plate. I use Thomas Hardwick's, and Ponting's collodions, sensitize in a 35-grain bath, wash in distilled water, place in bath of albumen, (1 egg, 10 ounces water, 40 drops ammonia), drain and well wash, dry, &c.

I expose, develop with pyro, only 2 grains, strengthen with pyro, acetic and silver, get a very good picture. Fix in hypo, and on drying, in four cases out of six, the film splits up in fifty pieces, and leaves the glass. You will see I have used three good collodions, separately, hoping to get rid of the difficulty, but without success. Can it be in the bath? for even with wet plates it frequently serves me the same.

Yesterday I dried a plate before fixing, to see if it was the hypo, but before it got dry all over, I heard a *crack*, and in ten seconds the film was in twenty pieces, one of the best negatives I ever took; I clean the glass well, and let the film well set. I have dried by heat, and also spontaneously.

If you can assist, you will greatly oblige, yours obediently,

A Perplexed Amateur.

[Our correspondent appears to take all the precautions which ought to secure immunity from splitting of the film. We have occasionally had it on using alkaline hypo, or on using cyanide; but not often. Thorough cleaning of the plates, and thorough drying before use, are the only remedies we can recommend, changing the collodion, or coating first with gelatine, might also be used. Can any of our correspondents help a "Perplexed Amateur?"—Ed.]

The Nascent State.—The word nascent is from the Latin word, *nascens*, and signifies being born. When water is decomposed, the two gases, oxygen and hydrogen, as they are being evolved, are said to be in the nascent state. In this state they are more ready to unite with other substances than they are after they have remained awhile separate. The same is true of other elements; just as they are in the act of being decomposed, they are more ready to form new combinations. This property is rendered available in chemical manipulations; combinations are formed by presenting the elements to each other in the nascent state, which it would be impossible otherwise to effect.

Talk in the Studio.

Photography at King's College.—We have pleasure in announcing that Mr. George Dawson, M.A., has been appointed lecturer on photogrpahy at King's College, in place of Mr. Sutton, resigned. Our readers are familiar with Mr. Dawson's papers, read at the North London Society, and published in our columns. The college has secured in him an accomplished scholar, a sound chemist, and a first rate practical photographer. As he has been engaged before in the work of tuition, he is well fitted for the task he has undertaken. We can congratulate the North London Society on the circumstance, securing them the continued presence of a member whose premeditated residence in the country would have been to them a great loss.

Photographs of Volunteers.—We had recently an opportunity of inspecting a very elegant album, which, filled with portraits of members of the London Rifle Brigade, was presented to the Lady Mayoress by Mr. D. Combe, of Cheapside, a sergeant in the corps. The album was bound in green velvet, ornamented with gold. The portraits were of those members to whom colours, bugles, and other prizes were presented on the 19th of October at the Crystal Palace. The portraits were taken by Mr. Combe, and many of them possessed much excellence. Lady Olliffe expressed herself much gratified with the present, as a gratifying *souvenir* of an occasion she would always remember with interest and pleasure.

The Small Suburban Society.—A provincial member writes:—"When is the next meeting of the South London Society? I am coming to London, and should much like to be present to express my feelings in favour of the Memorial. I think we are the most plucky of all the societies, although such a 'very small suburban,' &c. &c. &c."

Episcopal Photography.—*Punch* says: "Dr. Thompson, the new Bishop of Gloucester, is stated to be an expert photographer. Lord Shaftesbury begs us to add that his last creation is also an ecclesiastic of the decided school, and, in fact, that all his views are positives!"

Photography in the Exhibition at Florence.—The Italian correspondent of the *Daily Telegraph*, whose description of, and criticisms on, the Florentine Art Exhibition, are well worth reading, makes the following remarks on the photographic department. We shall be glad if a similar verdict be recorded at South Kensington, next year:—"The photographic gallery now consists of millions. There are portraits of all sizes and shapes—landscapes, architecture, and sculpture. I really think the best pictures are from the hands of a gentleman, whose English name and title—"Warren Vernon, 'amateur'"—attracted my attention. Some of his landscapes are beautiful. The medals for this branch of art are not yet allotted.

Child Poisoned in a Photographic Van.—On Friday evening an inquest was held by Mr. C. C. Lewis, at the Red Cow, Chapel-street, Stratford, on the body of Henry Giblett, aged two years and six months. It appeared that the deceased accompanied some other persons into a photographic van in Bridge-road, Stratford, and as they were having their portraits taken he suddenly became alarmingly ill, and by the time Mr. Kennedy, the surgeon, arrived, had expired from the effects of a quantity of iodide of potassium, which it is supposed he swallowed out of a phial which was in a cupboard. The jury found an open verdict, that the child died from the effects of the poison, but how administered there was no evidence to show. *Morning Chronicle.*—[Cyanide of potassium is most probably meant, although the iodide is a poison.—Ed.]

Bromides in Dry Collodion.—The following extract from a letter just received from a correspondent who had had some trouble in getting good results from dry plates, will interest some of our readers. "By following your advice kindly given me of adding half a grain of bromide to the ounce of collodion, "Ponting's," I am enabled to work the Fothergill process with almost certainty. I have just returned home after exposing two dozen plates stereo, some exposed a week after preparing, and developed a month after exposure; others at times to exposing a month after preparing, and develop a week after exposure. all good ones."

To Correspondents.

Membership in London Photographic Societies.—We have had several enquiries recently as to the mode of becoming members of the London Photographic Societies. It is necessary to be proposed by a member, and the election is by ballot. The subscription to the parent society is a guinea a year, and a guinea entrance fee. To the North London and South London Societies the annual subscription is half a guinea.

A Subscriber from the Beginning.—The definition of the picture enclosed appears pretty good, but it is straining the lens slightly to use it for card portraits, and you are too near the sitter when you use a lens of such short focus. The proportion of background, &c., has a great effect in influencing the appearance of shortness or tallness; a standing figure alone without accessories of any kind to give the suggestion of relative size, generally looks too tall. This effect is materially enhanced, if there be as much space underneath the feet as above the head. It is a difficult thing to lay down absolute rules for such cases; but the following may be taken as an approximate guide: the length of a card picture is from 2⅝ inches, to 3⅜ inches; a standing figure of about 5 feet 6 inches in height, will appear in fair proportions if it be from 2⅜ inches to 2¾ inches, being about a quarter of an inch beneath the feet, and three-quarters of an inch above the head. Your figure is much too large, in proportions, for a card portrait. You state that the lady is short, and yet you have the figure upwards of 3 inches high. It should probably be about 2½ inches high. 2 The camera for a standing figure should be placed opposite the chest, and quite parallel to the figure; for a sitting figure it may be opposite the head and tilted a little.

J. S.—Your card picture is in many respects, for an amateur, a very good one indeed. To neutralise your toning bath, make a solution of carbonate of soda, and add a drop at a time, testing between each addition with blue litmus paper, until it ceases to turn the test paper red.

Tyro.—The fault is not in the paper. It is manifestly imperfect fixation. Where the process appears to have been conducted so perfectly *en règle*, it is very difficult to fix upon the point of error. The hypo solution has been too weak, too many prints have been fixed in it, they have stuck together, or the hypo has been a bad adulterated sample; but which of these causes we cannot say. Possibly the toning solution has been acid, and there has been some decomposition of the hypo. The November meeting of the South London Society was held last night.

Hope.—Send us your address, so that we may communicate with you direct.

Ignis Fatuus.—The material for burning in Moule's Photogen is sold ready prepared. 2. We do not remember the price; about 8d. per lb., we believe. 3. Wherever it is used, there must be a flue to conduct the products of combustion carefully into the open air. 4. Some use of screens is important to a proper control of the light. 5. It would be dangerous, if improperly used.

Wm. Barnett.—A bromo-iodized negative collodion is best suited for iron development. There are several good ones in the market; but as we generally make our own, we are not in a position to recommend any especial maker. We have heard that of Burfield and Rouch, and also that of Mr. Hughes, highly spoken of.

F. L G.—A weak iron developer acts more slowly, and gives more density. A strong one acts more rapidly, but does not give so much intensity. Shorter exposure may be given where a strong developer is used. We prefer the iron solution made a little time before use. Never add silver to the iron developer. Acetic acid is better than citric with iron.

Ram Chunder Rao Bulvunt.—We have replied in the Photographic News all the letters we have received from you; but it is impossible to answer all your queries at length, as some of them would require complete treatises. Procure, if you can, "Hardwich's Manual of Photographic Chemistry," and some of the shilling instruction books. If you can, get Mr. Hughes's recently published "Principles and Practice of Photography." You can get the "Photographic Teacher" of Messrs. Le Page in India, as we know they keep it. Their London house knows nothing of any order or payment for the "Photographic Almanac." You had better get the agents in India to order a copy for 1861 and one for 1862 specifically, and they will doubtless be sent to you. In taking portraits in the open air, secure a position near a house or a wall, to obtain some shadow. 2.—We can only give you general hints for a glass room here. Let it be about 30-ft. long, 15-ft. wide, and 12-ft. high. 20-ft. of the roof glass, 10-ft. for the part above the sitter, dark. If convenient, all the sides glass, and plenty of blinds and screens to shut off light from any part where shadow is wanted. 3. Your collodion is probably too old. Make some fresh, and add to it. The formula you name is very good. 4. For landscapes you can either use a tent or dry plates. Collodio-albumen plates would suit you best. 5. Your prints are a little under-printed, but they indicate that the negatives are under-exposed and over-developed. They are also lighted too directly from the front. 6. The holes which occur in the negatives in the process of printing, seem to indicate that the varnish is not hard enough, and that more care must be used. 7. Add more acetic acid to your developer, and use it weaker. The Rev. J. Lawson Sisson's dry process was published in our pages some months ago. The only available method of taking portraits by artificial light that we know of is by the aid of Moule's Photogen.

Amateur.—The blue-tinted glass is, we believe, rather expensive, but we do not know the price. It shuts out some light, and is not of much service. The white sheet-glass is best so far as lighting is concerned, but it is apt to "sweat," and become dull. We should use a common sheet of glass of as good a colour as possible, consult a respectable glazier, and tell him your especial requirements. Both negative and printing in your reproduction appear very good.

An Enquirer.—The term "a German lens" is too indefinite to enable us to offer an opinion upon it. We have seen some of Jamin's lenses which were good. If you approach too close to the figure with a lens of short focus, you will get an unnatural effect. Your negative has been much under-exposed. The stains have probably been caused by allowing the developer to run into streaks, causing increased development.

R. G.—We can only advise you to repeat your application to the secretary. We were not aware that the exhibition was closed, as we have been looking out for some intimation of the award of prizes; but have not received any answer to enquiries ourselves, nor have we seen any intimation in the Society's organ. We believe the secretary has been much pressed with his private duties lately, and the position in the society is honorary.

Several other Correspondents in our next.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 168.—*November* 22, 1861.

ON MOUNTING PHOTOGRAPHS.

BY G. WHARTON SIMPSON.*

There are few things which contribute more to the general perfection of result in a picture than the mode in which it is mounted; and, as most photographers know, much of the permanency depends upon the adhesive material used in mounting. As but comparatively little attention has been given to this subject, I propose very briefly to devote a few words to the general question.

The first point to be considered will necessarily be that of trimming and shaping the print preparatory to mounting. In deciding the shape to which a print should be cut, whether rectangular or circular, oval, cushion, or dome, three considerations will weigh: first as to how much of the print makes a good composition; second, as to whether the corners, &c., are perfect, and third, the general contour and character of the lives in the picture. No specific directions can be given regarding the first point; nothing but good taste and a knowledge of the laws of composition can guide the photographer in determining how the picture will gain by the retention or exclusion of an inch, more or less, of the subject in his negative. His technical taste will, however, readily guide him to the rejection of dark or ill-defined corners, unless indeed they aid the composition in some degree. I remember some one exclaiming, when examining some of Wilson's instantaneous sea pieces, recently exhibited as single pictures about $4\frac{1}{2}$ by $3\frac{1}{2}$, in each one of which the dark corner produced by loss of illumination and definition at the edge of the lens was present, "What a pity Wilson did not vignette these prints, or cut them oval or circular, so as to get rid of these dark corners!" "That," replied another gentleman, who knew Wilson, "would have entirely frustrated the intention in leaving them, which is to force the lights, and by contrast give brilliancy to the prints, as they are from very thin negatives." This is an expedient, however, which should rarely be used, and then sparingly. But it illustrates that there are occasions when power may be added to the composition from the retention of a dark corner imperfectly illuminated or ill-defined.

The best shape for the print will often be governed by the prevailing lines in the picture, and especially by the general character of the outline. Where a number of parallel lines, vertical or horizontal, prevail in the subject, an oval or circular shape will often materially help the picture, and prevent the formation of angles, which must become striking if the rectangular shape be adopted. On the other hand when the principal lines fall in curves, the rectangular shape will be most suitable. In no case, however, is a perfect square desirable. The oblong form should in all cases be chosen: whether the greatest length should be vertical or horizontal, will be governed entirely by the subject.

It is never desirable in shaping the print, to follow the outline, or principal lines of the picture. If the picture be vignetted, it will rarely look well cut to an oval, circle, or dome; the corners should in almost all such cases be left square. The object should be to secure harmonious variety, and by the shape of the print to give the utmost value to graceful lines, or to distract attention from awkward forms. Another purpose may be sometimes gained by the shape of the print. It sometimes happens, especially in architectural subjects, that in obtaining a view of certain objects, it is immediately surrounded by others of less interest, which cannot be entirely removed without spoiling the picture. Where vignetting cannot be, or has not been, used to partially ignore these intruding elements, then the circular or oval form may be adopted with advantage, which by cutting away portions of the objects not required, at once gives importance to the principal figure left alone in its integrity. These, of course, are but general hints, not absolute rules. I may here remark that except where the exigencies of the photograph imperatively demand it, on account of dark corners, &c., I think that the shape styled by photographers the "cushion" shape, should generally be avoided as meaningless and inelegant. In most cases where it is used, the perfect rectangular shape would be much better. Where the corners are rounded, however, care should be taken to avoid a sweep which leaves it uncertain whether it is a flattened circle, an imperfect oval, or a cushion.

I may here add also one word more on the cutting out of card pictures. These are, of course, always best left rectangular. But it is an important point to remember that the due proportions of stature are chiefly indicated by the amount of space at the top and bottom of the figure. The size of the picture is generally from three inches and five-eighths to three inches and three quarters long. As a general principle, the amount of background above the head should be from half-an-inch to three-quarters of an inch, and the space below the feet, not more than a quarter of an inch. The exact amount will vary, of course, with the stature of the figure, but these remarks apply to a middle height. I may add also that it is a good thing to adopt a standard scale of proportion in taking such portraits, in order to give the pictures the value of suggesting truth in this respect. About half-an-inch for each foot in height would be found a good approximate scale for standing figures.

The best mode of shaping is to proceed as follows: If the prints have been rolled up, and are, therefore, inclined to curl, roll them the reverse way on to a roller and leave them for a few minutes, at the end of which time they will lie straight. A thick piece of plate-glass cut to the required size and shape is the best guide, as it enables the manipulator to see exactly the position and amount of picture included. I may here describe a very good contrivance described to me a day or two ago by Mr. Samuel Fry, which he had made for cutting out the card portraits. It consists of a plate of copper with an aperture the size and shape of the photograph. At each corner of the aperture there is a slight slit, proceeding, both vertically and horizontally, a little into the copper, so that in cutting, the knife passing into the slit, cuts the corner of the print clean, which it would be somewhat difficult to do if the knife could only just pass up to the corner. A sharp knife or old razor may be used to cut with; and a piece of glass, or a piece of smoothly planed lime-tree, to cut upon. The latter is most valuable, as it does not so readily dull the edge of the knife; and unlike other woods, its grain and texture are sufficiently homogeneous to allow the knife to pass without the vibration which gives a ragged edge. The utmost neatness and skill in getting a clean cut edge, free from jaggedness is imperative.

The proportion of margin is another subject on which the educated will be the best general guide; but upon which a few hints may be useful. Few things contribute more to give value to a print than a respectable margin; it is nevertheless by no means an uncommon thing to see very

* Read at a meeting of the South London Photographic Society, on Thursday, November 14, 1861.

fine pictures spoiled by shabby mounting. Nothing would be more difficult than to lay down any absolute rule on such a subject; but a very fair approximation to a rule may be obtained by deciding that the margin on the sides should never be less than one-third of the breadth of the print, and on the ends, not less than one-third the length. With small prints a margin of not less than two-thirds of the length and breadth is desirable for the best effect.

Under some circumstances the proportion of half the breadth for the side margins, and half the length for the ends will give a good result. But I have heard this principle objected to by persons of taste, as tending to formality and stiffness; it being urged that all proportions consisting of parts of even numbers tend to that formality. I have heard some attempt to establish a principle based on the analogies of musical science; but I fear that it would be difficult and unsafe to lay down definite rules on a subject which must largely be governed by feeling and educated taste.

A very excellent effect is produced by a narrow margin of india-paper immediately around the print; or of what is now commonly used as a substitute, a tint produced on the mounting board by lithography, in imitation of india-paper. This tint often gives great value to the whites of the photograph, and general relief to the tone of the picture. In some cases a good effect is produced by leaving a somewhat larger margin at the bottom than the top. In card portraits, for instance, it is better to leave about half-an-inch at the bottom, and about one-eighth of an inch all round. In all cases it is desirable to avoid intersecting corners; that is a line drawn diagonally through the mount, should not intersect the corners, first of the india-paper tint, and then of the print. Where the corners thus intersect, the effect is inevitably formal.

The next point for consideration is the best adhesive material, and the best method of using it. A great variety of materials have been recommended for this purpose, amongst which gum, dextrine, pastes of various kinds, glue, india-rubber, &c., have been chiefly used, and each has had its advocates. I do not propose to enter into any extended discussion of their respective merits, but just to offer one or two remarks on the subject.

The qualities necessary in any such material are that it should be easy to prepare, easy to use, efficient when used, and free from deleterious effect upon the photograph. Gum has the disadvantage, if thin, of sinking into the paper and showing on the face of the picture. It has moreover the tendency to rapidly turn acid, and if used in this state it injures the photograph. Making it with boiling water reduces the tendency to acidity or decomposition; and if made thus and used sufficiently thick, I think it may be used without disadvantage. Dextrine I have not used, but I believe there is no positive objection to its use. Of the various kinds of paste that made of starch is preferable, and if used fresh, is, I believe, perfectly safe. I prefer the patent starch, in powder, and without the blue tint for my own use. I may here describe a simple and efficient method of making it. I take a teaspoonful of the powder, and put it into a common marmalade jar, this is then mixed with the smallest quantity of water, which will make it into a thick paste. When it is rubbed perfectly smooth, boiling water is poured on it, the whole being rapidly stirred. Sufficient boiling water is used to make a thick transparent jelly, and one good teaspoonful of the powder will make a jarful of paste. This will keep good a few days in summer, and longer in winter. It is easily made, easily used, efficient, and will not, if used properly, injure the photograph.

Glue, gelatine, isinglass, &c., are used by some. Of these I think good Scotch or Russian glue will be found best. This for persons only mounting occasionally will be found troublesome to prepare and use, but it is very efficient, and I believe safe.

I may here refer with advantage to some experiments undertaken, and detailed to the Photographic Society of Scotland a few years ago, by Mr. Colin Sinclair. His object was to determine the effect upon the permanency of the print exercised by the various materials used for mounting. I will read one or two extracts from his report.

"I prepared a small quantity of each of the substances already named, (starch, albumen, isinglass, and gum-arabic), in separate dishes, and selected two of Mr. Tunney's photographs, one of them of the brown tint on albumenized paper, the other of the black tint on plain paper. I cut each of the two prints into five pieces, the fifth piece being laid aside for future comparison, and then distributed the four pieces of each picture over the four dishes containing the different materials, so that there were two pieces completely immersed in each dish. They were kept there for one month.

"I would have allowed them to remain longer in this state, but the pieces became so fragile, that I could hardly remove them from the liquids in which they were immersed. After cleaning the pieces, I mounted them along with the fifth piece, so as to show the relative effects on each, and I now lay the mounted results before you.

"It will be observed that the brown photograph on albumenized paper has suffered the most, especially the piece that was immersed amongst the albumen,—it has given way very much; the pieces that were amongst the isinglass and the starch are slightly affected; that which was in the gum is the least changed of any, while the black picture on plain paper has come out of all the four different substances much the same as it was."

Conceiving that it might be more satisfactory still to test the keeping qualities of pictures mounted with these materials, he took two other photographs and cut them each into five pieces, mounting four of the pieces, each with a different material, and keeping one piece unmounted for comparison. These mounted pieces were then placed in a damp cellar, where all the conditions generally considered averse to photographs were present in an exalted degree, and kept there for twelve months. At the end of that time they were submitted to the Scottish Society. I will read a brief extract from the report. Mr. Sinclair says :—

"The fifth piece, lying on each cardboard in juxtaposition with the mounted pieces of the pictures, shows the original colour, from which it will be observed that the whole tone is somewhat changed, but still indicating the superiority of the starch and the gum-arabic for mounting photographs.

"In the first experiment—that of steeping—the plain paper photograph, of a black colour, was less changed than that on the albumenized paper; but the result is reversed in the two mounted pictures—the one on plain paper, of a brown colour, being more injured than the other. This may be partly accounted for by the black-coloured picture having been a stronger print. The four photographs thus tested had been well washed with warm water, otherwise they could not have withstood the treatment so well as they have done, as is evidenced by the third picture in the hands of the members, which from its tone did not appear to have got justice in the washing, and was only about a fourth of the time in the cellar along with the others.

"As regards convenience of application, I prefer starch when mounting photographs, as it can be used with greater facility and cleanliness than gum-arabic, which, however, is very useful for an occasional picture, as it is inconvenient and not worth while making fresh starch every time an amateur requires to mount a few pictures."

From these experiments it would appear that Mr. Sinclair found starch and gum the most conducive to the well-being of the photograph. My own predeliction is in favour of starch, simply because I have found it so easy to prepare, and because as it will not keep, it must be prepared fresh; there is not, therefore, the same temptation to use it when unfit, which there is when a bottle of gum it kept for occasional use. I have heard the objection used to starch that it might generate acid even after the picture is mounted. I have no fear, however, that the dry particles of starch, by which my prints are made to adhere to the mounting-board, will produce me either sugar, alcohol, or acetic acid.

There is, however, another consideration which, under some circumstances, will influence the decision as to the adhesive material to be selected. There are two sources of trouble in mounting to which I have not yet adverted—curling and cockling. The cause of both these troubles is this: the print on being coated with paste or gum becomes saturated with moisture and expands, it is mounted on the board in this expanded condition, and as the moisture evaporates it contracts again to its original size, or even less, and draws with it the board on which it is mounted. Where there is a margin of board all round the print, "cockling," or uneven contraction often results. It will readily be seen that those substances which contain the most moisture, such as gum or starch, will produce those evils in the greatest degree. Where the pictures are mounted with a margin, this is an important consideration, and for this purpose it will be found that glue causes the least trouble. In using it the print does not expand much, and there is consequently little contraction. The curling, &c., may also be obviated by sponging the mount before laying down the print, so that both shall be equally expanded. The plan described some time ago by Mr. Stuart, of Glasgow, is also a good one for preventing this defect. Each print is covered with starch paste before trimming. and then dried. When they are to be mounted they are trimmed and shaped, the board, slightly wet, and the print placed upon it in position. The two are then passed through a lithographic press, which brings them into firm contract and completes the operation.

I may here mention a little hint which will be found of great service to those who have large numbers of card pictures to mount. When the prints are very stiff and dry much, it is difficult to cover them with the starch, without their curling up, and smearing the surface. To prevent this take a clean sponge and damp a few dozen before pasting them, they will then lie perfectly flat, and cause no difficulty. Although this involves two operations it will be found an actual saving of time.

I will, in conclusion, just refer to the use of india-rubber paste. This is scarcely suitable for general mounting purposes but is invaluable for fixing prints in albums or scrap-books. A slight touch of the paste at each corner attaches the print to its place in the scrap-book, and keeps it perfectly flat, without the slightest contraction, or "cockling." The paste is made by dissolving shreds of india-rubber in chloroform or benzole.

I now invite inspection of a variety of specimens I have brought to illustrate my remarks, and add, that the bulk of them—all those with the India paper tint—were mounted by Mr. Fox, of Little Britain, whose neatness, skill, and taste, in mounting generally, I can commend in the highest terms.

I have not said anything here of hot-pressing or rolling, but I may conclude by observing, that I consider it indispensable to perfect results.

PHOTOGRAPHY ON WAXED PAPER.

BY DR. LORENT.

For the representation of animated nature there is certainly no better process than wet collodion. Albumen, or dry collodion, claim the preference of the photographer when he desires to take architectural views and other inanimate objects, when the dimensions of his pictures do not exceed 21 by 17 inches. But when a larger size is required, and especially for the purposes of the travelling photographer, no method is comparable with that of photography on paper, not only from the facility of its manipulations, but also for the lightness of the travelling equipment and the certainty of the results. I must confess myself astonished that this method is not more generally practised, for the results may favourably compare with those obtained on glass. If the proofs are not quite so sharp, they present more stereoscopic effect, which is always pleasing, especially in large pictures intended to be viewed from a distance; besides, there is more *colour* in positives obtained from paper negatives.

I always employ waxed or turpentine-waxed paper; albumen paper does not keep long enough when dry, especially during summer. As for albumenized waxed paper, it keeps very well, but the albumen leaves the paper too readily when rolled. Paper simply waxed gives the same degree of sharpness if the focus has been accurate during exposure. Another advantage attending its use is, that it does not discolour the solution of aceto-nitrate of silver which then requires to be purified by kaolin or other means, and causes a great loss of time in filtering at every preparation of the sheets of paper.

It is best not to choose too thin a quality of paper, as it shows the unevenness of its texture by transparency. I always use Marion's paper marked No. 112 in their catalogue.

It would be superfluous to enter into details intended for beginners, or into a description of the method of waxing which is a long and tedious operation, and which the photographer would best avoid by purchasing the paper ready waxed. I therefore proceed to the first operation.

Iodizing the Paper.

Of the different solutions proposed for this purpose, that which has constantly given the best results is composed of

Distilled or rain water	1000 parts
Iodide of potassium	30 ,,
Bromide of potassium	10 ,,
Iodine (pure)	½ ,,

The iodine will quickly dissolve in a concentrated solution of the two salts of potassium: for that purpose, dissolve these latter in a small quantity of water, and then add the iodine, and after the solution is complete, the remainder of the water.

The waxed paper is floated upon the solution, and afterwards wholly immersed in it with the aid of a glass rod. The greasy surface of the waxed paper usually presents some difficulty in becoming moistened with the solution, but it may be facilitated by brushing the surface with a camel's hair pencil. Immediately the iodine comes in contact with the paper, it colours the starch contained in it of a violet hue, which is advantageous in the succeeding operation of sensitizing, and serves to fix the time of contact with the silver bath, by the change produced in the colour of the paper.

We can put in the same bath a dozen to twenty sheets of paper in succession, according to the quantity of the solution, which ought to cover them completely. The whole pile of paper should remain immersed four to six hours, then withdrawn sheet by sheet, and suspended to dry in a place free from dust.

When the sheets of paper are quite dried, they are placed in a portfolio, where they may be kept an indefinite time. I have made use of paper that has been iodized three years, and the results obtained were as good as upon paper newly prepared. It is probable that the paper continues in good condition as long as it remains coloured by the iodine.

The bath of iodide of potassium may be used until exhausted; every time a number of sheets are prepared, it is found that all the free iodine being absorbed, the liquor loses its orange yellow colour, and assumes that of a pale straw yellow; before using it again, some crystals of iodine should be added, until it resumes its primitive colour.

Sensitizing the Paper.

Make the following solution—

Distilled water	1000 parts
Nitrate of silver	100 ,,
When dissolved add—	
Glacial acetic acid	200 ,,

It is well to prepare two quarts of this solution in two separate bottles; the first will serve to sensitize the paper, the second to refill the first bottle as fast as it is used, and also to furnish the aceto-nitrate of silver solution which is mixed with gallic acid during the development of the negatives: for a solution which has served for preparing paper would form a precipitate too quickly by decomposing the reducing agent.

In sensitizing the iodized paper, we can, if desired, have the image on the surface, or which, I believe, is preferable, in the texture of the paper. If we float the paper upon the solution without immersing it, and leave it until the back of the paper changes from violet to yellow, the image will be impressed on the surface exposed to light; but if, on the contrary, the paper is immediately immersed in the solution by means of a glass rod or a soft brush, the image, during development, will at first show itself on the back of the paper; upon examining the paper on the side which has been exposed to light, the image will not appear very distinct by reflected light; but when viewed as a transparency, we shall be astonished at the amount of effect and detail apparent.

In either case, immediately the paper is floated on the aceto-nitrate of silver in a dark room, or one lighted by a small taper, or illumined through green or yellow glass, it must be examined to see that no bubbles have formed on its surface. Bubbles manifest their presence in the subsequent operations, as the paper does not change its violet colour in those places which are not moistened by the nitrate of silver, and if we are slow in removing it. there will be a difference in sensibility at the spot, and, of course, a blemish in the picture. When the paper has assumed a pale straw colour, it is allowed to remain yet three or four minutes, to make sure that there is no undecomposed iodide of potassium in the paper, then it is lifted out, held to drain a few moments, and then immersed in a dish containing distilled water.

If the paper is somewhat thick, no harm will result if it be allowed to remain in the aceto-nitrate bath ten or fifteen minutes; but on the other hand, if any iodide of potassium remains in the paper, the image will be covered with a quantity of small white spots, insensible to light, which necessitate a tiresome task of retouching, and which is sometimes also very difficult; this accident will sometimes occur in spite of every care, owing to the bad quality of the paper.

After having prepared the last sheet, which is allowed to remain at least five minutes in the washing dish, all the sheets are removed one by one, and dried between sheets of blotting-paper which is twice changed. The paper is afterwards gummed round the edges with a solution of gum-arabic, and they are fastened by it to the back of the negative frame. We can place the prepared sheets of paper behind a sheet of white glass, fixed within the negative frame, without prejudice to the sharpness of the image; but then the frame becomes much heavier, which forms an important consideration when working a large size, and in travelling there is the risk of breakage to be added. Some photographers recommend a repeated and prolonged washing to avoid granulation of the paper, and to make it keep a long time; but the granulation is due to the bad quality of the paper; and with respect to its keeping, it may, perhaps, be useful if we aim only at obtaining a view of an edifice, without attaching any value to the quality of the proof. If, on the contrary, we desire to obtain fine negatives, we must expose the paper and develop the image as soon as possible after sensitizing. The paper which still retains traces of humidity will yield the best proofs.

It may be asked, why employ waxed paper if it will not keep well? I reply, waxed paper will always hold good for a day. The wax stops the pores of the paper, and renders it homogeneous, and prevents the nitrate of silver from reacting upon the ligneous fibre. If, from any cause, we are prevented from making use of sensitized paper during the day, we can reimmerse it in the iodizing solution, where it will reassume the violet hue, but of a lighter tint than before, and may then be dried and preserved as paper that has been simply iodized.

After paper in several quantities has been prepared in the aceto-nitrate solution, the latter becomes stained by the reduction of the silver; it is only necessary to filter it to restore its clearness, or simply to decant it, because the particles of oxide of silver, if they are not too numerous, are carried off in the washing water; kaolin is never necessary to remove the colour of this solution.

A quart, or three pints of the solution of nitrate of silver of the strength indicated above, will serve to prepare 50 sheets of paper, 17 + 22 inches; it then becomes impoverished in its salt of silver, but rich in nitrate of potassa. The old solutions are more sensitive, but also more quickly decomposed. The negatives they yield are never very strong; the parts that should remain white are sullied. During the course of last summer, I took at Venice 50 negatives, 21 + 32 inches; when the silver solution diminished, I always refilled the bottle with new solution. Upon the completion of my task, I precipitated all the silver in the bottle (which still contained 1,200 grammes of solution), with hydrochloric acid; the remaining liquid, after evaporation, which I did from curiosity, gave a residue of salts of potassa which weighed 65 grammes.

The time of exposure of the paper in taking a view, differs, of course, with the objective, the length of its focus, and the object to be copied. The distance of the object is of great importance; if it takes fifteen minutes to copy a very near edifice of a sombre colour, five minutes will be sufficient for a statue in white marble with the same apparatus.

(*To be continued.*)

PHOTOGRAPHIC CHEMICALS:

Their Manufacture, Adulterations, and Analysis.

Phosphoric acid.—By far the most important phosphorus compound, both scientifically and commercially speaking, is its highest oxide, phosphoric acid, which consists of one equivalent of phosphorus to five equivalents of oxygen. This substance is formed whenever phosphorus is burned with free access of air; in the state in which it is then produced it is in what is termed the anhydrous condition, and is put to a great variety of uses in chemistry and other branches of science on account of its intense affinity for water, an affinity, the energy of which surpasses almost everything of the kind known in chemistry; flakes of the anhydrous acid hissing like a red hot iron when they are dropped into water and uniting with the latter with a power which no chemical force can overcome without decomposing one of the constituents. It is on this account that anhydrous phosphoric acid is so much used for the purpose of absorbing water from gases, &c., which it does in a more perfect manner than any other reagent. It is prepared by burning phosphorus in dry air or oxygen gas. A small portion of phosphorus is rapidly dried between blotting-paper and placed in a small dish in the centre of a dry flat plate: it is set on fire by touching with a hot iron, and then immediately covered with a dry inverted bell jar of a capacity of about 200 or 300 cubic inches. The flakes of anhydrous acid produced by the combustion rise up and are deposited as a light snowy-looking substance on the sides of the jar and on the plate. If more acid be required, a fresh piece of phosphorus may be introduced when the first is consumed, and, the air in the jar being renewed by holding the latter up for a few seconds, the combustion is proceeded with as before. The resulting acid must be rapidly scraped off the sides of the jar with a flat spatula or card, and then transferred to a perfectly dry, well-stoppered, wide-mouthed bottle for future use. In this state phosphoric acid presents the appearance of white flakes, which rapidly deliquesce upon exposure to the air, to a colourless liquid, inodorous, not corrosive, and of intensely acid but agreeable taste. In combination with water or bases, phosphoric acid occurs in three different isomeric states which render the study of the phosphates peculiarly complicated and difficult to master. We will briefly glance at so much of these conditions as appear likely to be of use to our readers, and then confine our remarks to the modification generally met with.

Our readers are aware that most acids, when they form salts, combine with one equivalent only of the metallic oxide; thus, nitrate of silver is formed of one equivalent of nitric acid, and one equivalent of the oxide of silver. Nitric acid, therefore, is called a *monobasic* acid, as it requires one equivalent of base to saturate it and form a neutral salt. Tartaric acid, however, requires two equivalents of base to one of acid to form a neutral salt, and is, therefore, called a *bibasic* acid. Citric acid is an example of a *tribasic* acid, or one which requires three equivalents of base to one of acid to form a neutral salt. In speaking of the constitution of salts, it must, moreover, be borne in mind that *water* may, and does act as a base; thus, nitric acid is strictly speaking, a nitrate of water, &c., just as we speak of nitrate of silver. Now, in bibasic and tribasic acids, the two or three equivalents of base which are required to saturate the acid need not be the same base, we can have one equivalent of one base, a second of a different base, and a third of a third base; and, moreover, any one or two of these bases can be replaced by water. Thus, in chemical symbols, calling the radical of tartaric acid T; potash KO; and water HO, the ordinary tartaric acid would be represented by

$$\left.\begin{matrix}HO\\HO\end{matrix}\right\} T,$$

whilst acid tartrate of potash would be

$$\left.\begin{matrix}KO\\HO\end{matrix}\right\} T,$$

cream of tartar would be

$$\left.\begin{matrix}KO\\KO\end{matrix}\right\} T$$

and Rochelle salt (double tartrate of potash and soda).

$$\left.\begin{matrix}KO\\NaO\end{matrix}\right\} T.$$

It is thus seen that a monobasic acid has one vacant space, which always be filled up either by water or a metallic oxide, whilst bibasic and tribasic acids have respectively two and three vacant spaces, each of which must be filled by some substance having basic properties, but any different base may be used to fill up any space.

The difficulties in the way of a correct understanding of the different modifications of phosphoric acid will now be readily appreciated, when we say that this acid is capable of existing in all three states, either as a monobasic acid, known by the name of metaphosphoric or *a*-phosphoric acid; as a bibasic acid, called pyrophosphoric or *b*-phosphoric acid; and as a tribasic acid, known as *c*-phosphoric acid; and the complications are not lessened by the fact that these different acids are capable of changing one into the other, sometimes by simple ebullition of the solutions of their salts, and in other cases by ignition. Fortunately for photographers, the last modification—the normal condition of the acid, as it may be called, is the one easiest obtained and the most useful for their purposes, although from all varieties of the acid and its salts being known under the general name of phosphoric acid and phosphates, it has frequently happened that an amateur has got hold of the wrong body for his experiments; and as their properties are very different, the results obtained will be different from those anticipated. In the subsequent description we will confine ourselves to the ordinary tribasic phosphoric acid.

The solution of this acid may be readily obtained. When the anhydrous acid is dissolved in water, and the solution boiled for some time, it is quickly converted into the tribasic modification. In order to free it from some lower oxides of phosphorus which may possibly be present, the solution should be mixed with nitric acid, and evaporated until all the nitric acid is driven off. Upon heating this still further, the excess of water evaporates until what is left solidifies on cooling to a soft glassy substance, which is known as phosphoric glacial acid.

Another way to prepare phosphoric acid is to heat phosphorus in a retort with nitric acid. The phosphorus is oxidised at the expense of the acid. This process, however, is somewhat unsafe in inexperienced hands, and is, therefore, not recommended so much as the preparation by combustion. On the large scale, and when absolute purity is not required, phosphoric acid is prepared from burnt bones, which consist almost entirely of phosphate of lime. This plan is, however, not recommended for photographic purposes, as it is difficult to obtain it pure. A great deal of the glacial phosphoric acid which is met with in commerce is shamefully adulterated. We purchased some a few months ago at a respectable house, where we were assured it was pure. It was done up in little wide-mouthed ounce bottles, carefully corked and waxed over, and labelled "acidum phosphoricum." The acid was in nice-looking transparent lumps like glass. To our astonishment, when we attempted to make a solution of it, the lumps refused to dissolve in water, and upon examination turned out to be nothing but super-phosphate of lime with excess of acid. We have been particular in describing the appearance of the bottles, as we believe large quantities of this trash is imported from Germany, where the bottles are filled and got up in the manner above described. We need not say that superphosphate of lime, although an excellent manure, is not a good substitute for phosphoric acid, especially in photographic operations, where slight traces of impurities are often of great consequence.

Phosphoric acid may contain as impurities,—*Phosphorous acid*, which is detected by the solution giving a blackish instead of a yellow precipitate with subnitrate of mercury; *Metaphosphoric acid*, which is shown by its silver precipitate being white instead of yellow; *Sulphuric acid*, which occasions a white precipitate with chloride of barium, insoluble in hydrochloric acid; *Nitric acid*, which occasions the solution to evolve red fumes when heated with copper; *Ammonia*, which may be detected by the smell upon adding an excess of potash; *Lime*, which is precipitated by oxalic acid, after nearly neutralising with ammonia or potash; *Magnesia*, which is precipitated by adding excess of ammonia; *Arsenic*, which causes a yellow precipitate when sulphuretted hydrogen is added to the solution; *Sesquioxide of iron*, which causes a red colouration when a drop of sulphocyanide of potassium is added; and *Oxides of lead and copper* which are precipitated black by sulphuretted hydrogen.

The aqueous solution of phosphoric acid is of the consistency of a syrup when concentrated. It gives a white precipitate with baryta, strontia, or lime-water, or acetate of lead, does not precipitate chloride of barium, and gives with nitrate of silver, upon the addition of a small quantity of ammonia, a bright yellow-coloured precipitate.

Of the salts of phosphoric acid, which are of value in photography, we shall speak in our next article.

HINTS FOR WORKING WITH CLEAN HANDS.

Sir,—I seldom stain my fingers or my plates.

I use a pair of OLD worsted or cloth gloves for removing the plate from the bath to the frame, and a pair of leather gauntlet gloves (common housemaid's gloves will do), for developing.

The worsted or cloth gloves are very elastic, their former wear has worn down the pile, and the *ends* of the thumbs and fingers fit close.

Keeping my old winter gloves for this purpose, I have always two or three pairs at hand, and after a few plates, for fear of stains, I use a fresh pair.

I remove the plate from the frame by a pneumatic holder, but I only trust to it to bring the plate to a horizontal position, with the film upwards; then with one of the fingers of the hand which holds the plate, I unslip the lever of the holder.

The plate now being loose, it is easy to transfer it to the wooden plate holder (which I shall describe hereafter,) without injury to the film, as it rests partly ON the fingers, BELOW, and partly AGAINST the thumb at its side.

The coarse leather gloves, worn during this part of the operation, may be made more convenient and safe by a gusset of leather being inserted under the thumb, and by the ends of the fingers being rounded. I have always two or three pairs ready, in case of one pair, by accident, becoming wet through. Holding the plates as I have described, this would not affect the film; but it is disagreeable to work in wet gloves.

I send you models of my plate holders; the first is of glass, for 12 + 10 plates, say about 11 inches long, by about 4 inches wide; it has a thin strip of glass glued on to one end, which forms a sort of handle, and also keeps the plate from slipping while the collodion is poured on. The back of the plate and the surface of the holder being both dry and clean, the former resting on the cross strip, has no tendency to slip, and in pouring off the waste collodion, by the aid of the mouth of the bottle, it may be held nearly vertically.

The plate is thus covered to its four corners, and no impurity on its back can injure the bath.

The second holder is of wood. I varnish mine; it is so made that the developing mixture can hardly reach the hands, even if gloves were not worn. It is difficult to describe it—call it a *short*, *broad*, harlequin sword, with a guard between the blade and the handle, so contrived that all liquids poured on the blade shall run off without reaching the handle. A long slit in the centre of the blade allows the progress of the development to be examined.*

The developing plate holder rests on a tumbler or gallipot; this is placed on a low stool, which stands in my sink. The legs of the stool are of such a length as to raise the plate to a convenient height for watching the flow of the liquids; but as I keep the developing solution in constant movement, pouring it off and on frequently, the holder is more frequently in my hand than on the rest. All this is simple and inexpensive, and nothing can get out of order.

My first idea of these holders was taken from a French work, (Brebisson's.) At first I used only the glass holder, steadying the plate by inserting a small piece of wet blotting paper between it and the holder: it acted admirably, and was most convenient; but it does not save the hands from stains so well as the one I now use in developing.

Whatever may be the merits of the holder, I am sure that much of my success in avoiding stains arises from my having two holders, each kept for its own purpose; and from my having different sets of gloves, one set being used solely for removing the plate from the bath to the frame, the other being kept for the developing, fixing, and washing operations. When I used but one pair of "gauntlets," stains on the film were sure to appear after the second plate, sometimes after the first. I have the honour to be, sir, your obedient servant, N.

Photographic Tourist.

MY FIRST PHOTOGRAPHIC TOUR.†

The ancient city walls, said to have been laid so low by that terrible Fairfax, have many relics over which I frequently stumbled in my rambles about the town. In places these fragments are still tall and strong, but most frequently their rugged barriers of ancient masonry are mere mounds, and peering in their grim ruin from picturesque nests of luxuriant ivy, creeping, and flowering plants, and thickly growing grasses and weeds, help to form very pleasing pictures.

If you are fond of "close scenes," as we artists call them, you will find many such about Colchester: winding, narrow roads, ascending or descending and losing themselves in the shade of tall hedges and overhanging trees, through whose trunks charming glimpses are caught here and there of sunny hill sides and shady valleys, of heaven-pointing church spires, and clumps of rounded foliage, in all their varied hues and colours, and with a most pleasing diversity of harmonious light and shade. Not far from the town, and close by the village bearing their name, are the Lexeden Springs, where a choice collection of such views may be got, and from which spot I secured several sketches. One of the large shallow basin of pure, colourless and brilliant water, where the springs rise under the out-spreading boughs of some very fine trees; one, of a yet shadier nook, where the trees are more closely planted, and the glassy sheet of purely transparent water glides over gleaming, purple, green, golden, and ruby pebbles, breaking every now and then the monotonous little chattering sound with which it pursues its sparkling course with a tinkling musical splash or two; one of another spot where, diminished to a silver thread, it steals secretly amid the grass-blades, which, nevertheless, mark its way with a fresher and more brilliant green; and of yet another, where, passing under a rustic bridge, it grows bolder and broader, and flashes joyously from its sweetly quiet and beautiful little birth-place out and away in the full unshadowed glow of sunny daylight. Ah! many a happy hour, never, never to return, we spent in the scenes my memory can so imperfectly but tenderly recall; when the dear one, now no more, sat beside me with her needlework or book, and the camera began to take that place in my affections which I once thought nothing but my brushes and palette could ever fill. I can recall many such spots, the discoveries of as many never-to-be-forgotten rambles; but I have already sufficiently indicated for the purpose of our landscape photographers how rich this portion of the country is in their particular requirements, and may now turn to matters relative to my own experience in portraiture, &c.

Having procured better apparatus from one of the London dealers and so got ready for a second appearance as a Daguerreotypist. I secured apartments at a pastrycook's, nearly opposite the little old church tower with the clock, and, in a large front room with a big window, contrived to get my pictures, not very perfectly, it is true, but so far so, that, luckily enough, I succeeded in pleasing the greater number of my patrons. At first I used to place my sitter as near the window as I could, with one white screen on the shadowed side, but finding that the contrast of equal white and equal black was too harsh and strong when the model was illuminated in this "half and half" style, soon altered this, and placed the sitter very much farther in the room, with the face more fully towards the light, and with *two* white screens, one on either side. By so doing I lessened the action of the lighted parts, and obtained more even chemical results from the entire image, although the exposure was certainly more prolonged. I effected some improvements in this respect afterwards by using a metallic reflector in the place of one of the white screens.

Shortly after I came into this town, it was in all the ferment and excitement of the general election; flags were flying, bands were playing, ribbons, orange and blue, were displayed on hats, in button-holes, and bonnets; processions of carriages and equestrians were continually forming, headed by bands and banners; men bore huge printed placards stuck on poles, or hung about their necks, through the bustling thoroughfares near the committee-rooms; hot, strong, and loud arguments were heard in the tap-room and parlour of every inn, strife was rife, and physical arguments were unhesitatingly taken up when moral failed; stupid, fishy-eyed yokels, husky of voice, and uncertain of step, shouted for "*cheap beer*," and thin, sun-burnt, hard-handed women, shabby of dress, and hollow of cheek, cried earnestly for "*cheap bread*;" there were scramblings for half-pence, and burnt fingers among the eager poverty-stricken, quarrelling, and fighting scramblers, whereat gentlemanly practical jokers laughed uproariously, and their smarting victims grinned with difficulty. There was a fair allowance of bad blood spilt, and much good ale and wine; a good many hats were crushed, and many garments torn. Cheers and groans, applause and hisses greeted both candidates, who, of course, were both equally certain of success; many speeches were spoken, very few were audible, even little, gleeful, ignorant children were carried away by the common spirit, and had little party squabbles over their tiny blue and orange flags, and no portion of the population were more excited, more noisy, more seemingly deeply concerned in the interests at stake, than, as usual, the dogs, which, running here, there, and everywhere in hot haste, barked, and panted, and seemed as if the whole important business of the great event was dependent solely and entirely upon their most energetic and active superintendence and inspection. There was a strong display of ancient enmity, much spite, and no little malice, but there was an amazing deal of talk about friendship. Well-fed, fashionably-attired

* We intend submitting the model to some manufacturer; and it possibly may be introduced to the public commercially.—Ed.

† Continued from p. 522.

farmers, who seemed tolerably able to befriend themselves, talked continually and excitedly about "the farmer's friend," and poor folk talked energetically about "the poor man's friend," and reformers boasted "the friend to reform," and patriots "a friend to the country," and others about "the friend of the people," or "a friend to the town or county," or "the friend of commerce," or no end of boastful friends, to no end of objects and purposes, in apparently urgent need of friendly aid. For myself, I was heartily glad when all this fuss, and bother, and turmoil, and scheming, and plotting, and squabbling, and fighting, were over, the polling-booths down, and the town in its usual peaceable state.

Among my acquaintances here, were many an amateur, and one professional, follower of Daguerre. The amateurs were very earnest in the pursuit of excellence, but were a sadly long way from its attainment, although the professional gentlemen was certainly not much in advance of the rest; but they were all of opinion that the superior character of the more beautiful productions which they sometimes saw, not mine—oh dear no!—was due to the possession of some peculiar and never explained process, or jealously guarded secret, and was certainly not due to the process as practised by themselves; or, look you, "why couldn't they produce the same results." A foolish species of reasoning not yet extinct among amateur photographers, and which, as I afterwards heard, laid these particular individuals open to the cunning of a certain crafty Scotchman, who coming into the town in a house on wheels after my departure, and taking very good pictures, sold these simpletous all sorts of trivial or valueless hints—as secrets to which he owed his success—for sums ranging from five to ten and fifteen guineas; the said hints being merely such as he had derived from the *Journal* of the Photographic Society, a serial not then known in Colchester.* These amateurs seemed lost in wonder that I, a professional, had *no secrets*, and most of them thought but little of my pictures or myself in consequence thereof, but, although I saw all this very plainly, I, who would fain be an artist, could not stoop to the petty tricks of the charlatan.

My patrons here were very varied in position and character. I had bluff, hearty, honestly pig-headed, good fellows, whose pictures were to be taken "Oh, anyhow," or "Just as they were," being *only* to please the "*whims*" of their wives or daughters, and who scarcely deigned to give their finished miniatures a second glance; and I had finical little fops of scrupulously critical shopmen, with an intense horror of shadows on their faces and creases in their apparel. I had ugly women, with an inordinate appetite for flattery, for which every speech they uttered was full of fish hooks, whose pictures had "*never* been taken" (and never would be) "although they had sat ever so many times;" and I had pretty girls, who took anything but flattered portraits, with an air of perfect contentment. I copied precious portraits, the sole relics of the loudly lamented dead, some of which, *together with the originals*, I still have in my possession, the owners who so solemnly impressed me with the tremendous importance of preserving them from injury, never having called again for them. And I copied one wretched fading Daguerreotype of a private soldier, who had died abroad, for a poor old withered ugly woman, in patched and shabby poverty, who had positively gone without animal food for many months, and came a-foot from a village many miles away, in order that she might secure a copy of the sister's picture of a son who died four years before. Poor old girl! my dear little wife had some difficulty to refrain from embracing the dingy little old crone, so touched was she with the truth and intensity of her quiet grief, and undemonstrative affection. Then I had "ladies," who would insist upon so holding their hands that they resembled the stuffed gloves of a boys' Guy Faux, in order to display their rings; and "gentlemen," who were very indignant that the position chosen did not display the full costliness of their albert chains; in short I had, during the four months of my stay in Colchester, the usual amusing variety of sitters, and met in them the peculiarities familiar to every practitioner of our art, in its department of portraiture.

When I left Colchester it was to visit friends and relatives in London, and thus ended my first, although by no means my last, Photographic Tour, the humble account of which has, I hope, at least contributed to your amusement.

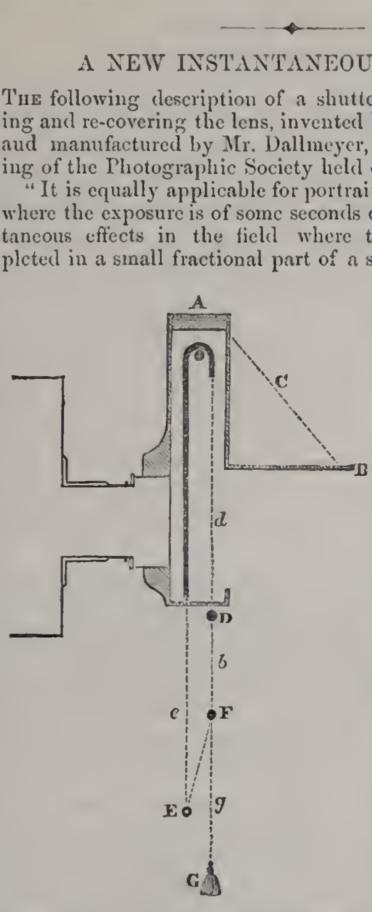
R. A. S.

* Only the other day I heard from a country friend that this same Scotchman does quite a large business in such secrets, having just received five pounds for "a background dodge," which has more than once been fully explained and denounced, both in these pages and those of our contemporaries.

A NEW INSTANTANEOUS SHUTTER.

The following description of a shutter for rapidly uncovering and re-covering the lens, invented by Mr. F. R. Window, and manufactured by Mr. Dallmeyer, was read at the meeting of the Photographic Society held on the 5th.

"It is equally applicable for portrait lenses in the studio, where the exposure is of some seconds duration, or for instantaneous effects in the field where the exposure is completed in a small fractional part of a second.



"It consists of a small box, A, which fits on to the hood of the lens. The front, B, when in use, is kept open by means of an elastic, C, and serves as a shade to the lens.

"Inside the box, at the top is a roller, working on points at each end. Over this roller passes the shutter, which is of a flexible material composed of wood strips upon leather; this is represented in the section we have given by the thick line. From each end of this curtain, or shutter, depend strings, *d* and *e*, terminating in the rings D and E. Another string, *f*, joins these rings together, and finally from the ring, F, placed in the middle of *f* proceeds the string *g*.

"By referring to the cut, it will be seen that when either ring, D or E, is pulled down as far as it will go, the shutter is entirely closed. If it be now desired to uncover the lens for a definite time, as for a portrait or dry plate landscape, the string, *g*, is pulled down, which will raise the shutter halfway, and fully uncover the lens. When it is wished to re-cover the lens, either of the rings, E or D, is drawn down as far as it will go, and the object is effected. If an instantaneous exposure, as it is termed, be desired, that is, one of only of a fraction of a second in duration, the ring, D, as shewn in the drawing is pulled down as far as it will go with the speed required, and this one movement will open the lens and also reclose it. It will be noticed that the after part of the shutter rising, the lens is uncovered from the bottom, and the foreground is the first thing exposed; and the front part of the shutter descending, the lens is re-covered from the top, so the foreground is the last thing exposed.

"This instrument, therefore, supplies what has long been a desideratum, the means of rapidly uncovering, *and* re-covering a lens by one continuous movement; which avoids shaking the instrument, and at the same time of giving to the foreground a longer exposure than to the sky, and remaining portions of the picture.

"The time of exposure with this apparatus is perfectly under control, the motion being made with the hand; a very little practice would suffice to enable the operator to regulate it with the greatest accuracy."

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 20th November, 1861.

At the adjourned meeting of our Photographic Society, several of the members presented the results of their summer excursions in various lands. Conspicuous among them were the views in Switzerland, executed by Messrs. Bisson, frères. Of these, the panoramas of Mont Blanc and Mont Rosa excited the warmest admiration, which surpass in excellence anything of the kind hitherto seen, both in perfection of the detail and the harmonious tone of the proofs.

A series of proofs printed from negatives taken by Major Russel's tannin process by M. Anthony Thouret, an amateur, excited much curiosity, and are very creditable to the talent of the operator, besides showing in a very satisfactory manner the capabilities of this new process. Some very excellent views taken by Taupenot's process, by M. Jean Renaud, displaying high artistic skill and taste, also called forth much admiration. M. Migurski also exhibited a striking collection of views in Russia, together with portraits and types of various races; these were taken by various processes; some of large dimensions obtained by enlargement, in iodised paper, in two seconds, were much admired.

There is a good deal of photographic litigation going on here at present. M. Quinet is especially prominent in litigation, and it could not well be otherwise from his practice of patenting other people's inventions, old and new. It is probable that M. Poitevin, whose name is so honourably associated with photolithography and carbon printing, will become involved in a law-suit with M. Fargier, of Lyons, who obtained at the close of last year a patent for carbon printing by a process identical with that patented by M. Poitevin in 1855.

Here, as in England, patents are granted without examination of the merit or originality of the claims; consequently, it frequently happens that patents are granted for the same invention to two or more applications. A much better practice obtains in the United States, where the Patent Office undertakes to examine into the originality of claims, and only grants patents to original inventions.

Some specimens of the photographs obtained without the employment of salts of silver by a process announced as discovered by M. Wothly, of Aix-la-Chapelle, and mentioned in one my letters a few weeks ago, have recently been exhibited. The results are remarkably good. M. Girard, who has made a chemical examination of them, thinks they are formed of gallate of iron. If such be the fact, the process by which they are obtained has no claim to novelty.

Ozone has been suggested by Gorup-Besanez as an effective and convenient agent, when properly applied, for restoring books or prints which have become brown by age, or been smeared or soiled with colouring matter; only a short time being required to render them perfectly white, as if just from the press; and this without injuring, in the least, the blackness of the printing ink, or the lines of the crayon drawings.

As examples of his results, the author mentions a book of the sixteenth century, upon a page of which several sentences had been painted over, by the monks of that epoch, with a black, shining material, so as to render them illegible, and of which no trace of a line could be detected. After 36 hours' treatment with ozone, the colouring matter was entirely removed, and the most careful scrutiny of the page failed to discover that any of the lines had ever been painted over. In like manner, a wood cut after Albert Durer, which had been smeared with a dark yellow colour, was completely restored to its original whiteness.

Writing ink may be readily discharged by ozone, especially if the paper be subsequently treated with very dilute hydrochloric acid, to remove the oxide of iron.

Printing ink is not attacked by ozone to any appreciable extent, unless the action be long continued. Vegetable colouring matters are completely removed by it; but metallic colouring matters, grease spots, and stains produced by fungi, cannot be obliterated.

As applied in the small way, the method consists in placing a bit of phosphorus about three inches in length, and half-an-inch in diameter, the surface of which has been scraped bright, in a wide necked glass carboy, or other large hollow vessel, pouring about as much water, at about 86° F., as will half cover the phosphorus, closing the vessel with a cork, and allowing the whole to stand until the jar is charged as strongly as possible with ozone, which usually occurs after 12 or 18 hours. Then, without removing the phosphorus or the water, the paper intended to be bleached, previously moistened with water, rolled up, and suitably attached to a platinum wire, is hung in the middle of the vessel. The cork is then replaced, and the apparatus is left to itself. The roll of paper is soon surrounded with the fumes arising from the phosphorus, and the stains gradually disappear. The rapidity of the operation of course depends upon the nature of the substance to be discharged—three days being the longest time required in any of the experiments. Prints which had merely become brown by age, and others stained with coffee, usually became perfectly white and clean in the course of 48 hours. The action of the ozone, however, must not be continued too long, lest some of the finer lines of the engraving should be injured. After all the spots have disappeared, the paper is strongly acid, and if allowed to dry when in this condition, would become exceedingly brittle, and also dark coloured. It is consequently necessary to remove the acid completely. In order to accomplish this, the paper is placed in water, which is frequently renewed, and allowed to lie there until a bit of blue litmus paper pressed against it is no longer reddened. The paper is then passed through water, to which a few drops of solution of soda have been added, and is spread upon a glass plate. this is slightly inclined, and a fine stream of water is allowed to flow over the paper during 24 hours. After the paper, upon exposure to the air, has become dry enough to be removed from the glass without risk of tearing, it is taken off. and pressed dry between folds of bibulous paper.

Proceedings of Societies.

South London Photographic Society.

The ordinary monthly meeting of this Society was held on the evening of Thursday, the 14th inst., at St. Peter's School-room, Walworth-road. The Rev. F. F. Statham, M.A., F.G.S., in the chair.

After the usual routine proceedings, the Secretary announced that the next meeting would be made special, to take into consideration a question of considerable importance.

Mr. Wall, the honorary secretary, then said:—I have to inform the members that the memorial addressed by this Society to Her Majesty's Commissioners for the Great International Exhibition was duly forwarded, and its receipt politely acknowledged. But although a circular has been addressed by the Commissioners to the secretaries of the sub-committees detailing the various applications for space, and urging such investigations as may tend "to do credit to the present state of national and local industry," photography is as yet unrepresented. It is true that the Commissioners have promised, since the receipt of this Society's memorial, that such a committee shall be appointed; but this promise is not yet fulfilled, and precious time is, consequently, being lost. Of all classes of exhibitors few need more time for the preparation of their various works than photographers, especially when such preparations must be made at the worst possible time of the year. It is, therefore, important, both to the interests of the art and the interest of its professors, that any investigations which may be necessary, should be promptly made; and such decisions as may be arrived at, quickly published; in order that British photography may do honour to the national character.

By way of hint to such of our professional photographers as may have greater respect for individual profit as opposed, in their thinking, to national gain, I may, perhaps, venture to point out to them, that so surely as the prejudice against English as opposed to foreign photography (which already shows signs of existence) is proved by next years great show, to be but too well founded, so surely will the encouragement and patronage which photography has met with in this country be, to a very serious and damaging extent, taken from them and bestowed upon their Continental brethren. While, on the other hand, if this country carries off the palm of photographic excellence, *we* shall gain crowds of patrons from other lands, and our art thus encouraged must necessarily march more rapidly upwards and onwards to perfection. We cannot, I think, whether as a society, or as mere individual lovers of our art, too frequently urge upon the photographic world the vital consequence of preparing *earnestly* and *thoroughly* for that glorious contest of nations of which this country will next year be the theatre.

Holding such opinions as I have ventured to refer to, then, your Committee, at our last meeting laid before you the memorial you so unanimously adopted, fondly hoping that their active energy and promptitude would find the most hearty welcome and appreciation in every section of what the *Daily Telegraph*, in respectfully naming this Society, calls "the great modern guild." I have no reason to believe this is not the case, but the editor of our late organ, *The British Journal of Photography*, strangely misconceiving the spirit and purpose of our memorial, has not only protested against it as an individual member of this Society, but denounced it as illegal, and satirized it to the best of his ability in the leaded type of a leading article.

Mr. Shadbolt holds that "such a document could not be adopted as that of this Society without previous notice of so important a measure being contemplated." Now, whether judged by our own laws, or by precedent and custom, I hold that the course we adopted cannot be questioned. If Mr. Shadbolt thinks otherwise, it is very easy to show cause for such a belief, until which is done little or nothing can be said in reply to this accusation.

With reference to the article in that gentleman's journal, it indicates chiefly that Mr. Shadbolt must have a very fertile imagination. Our memorial points out that a committee for the management of the photographic department is of vital consequence, and urges that such a committee be promptly organised. Surely no one will deny either the necessity for, or the non-existence of, such a committee. But our imaginative friend, the Editor, trembling with fear lest what he calls "a small, not to say a very small, suburban society" should prove a second Curtius, and leap into "the yawning gulf *supposed* to exist in the form of a vacant space where a committee for managing photographic affairs ought to be found," quite overlooked the fact that this Society, in its memorial to Her Majesty's Commissioners, never implied or intended that it should "sacrifice itself by leaping *bodily* into the void space." I trust, therefore, that this assertion will calm down the eager fears of our too susceptible censor, and convince him that there is no fear of this Society taking undue precedence of its elders, *unless they choose, by retreating, to leave their southern relative foremost in the van.* I trust, that as a society "established for the advancement of photographic art and science," we shall never be deterred by the fear of misrepresentation from taking any steps clearly and closely united with the duties we have voluntarily sought, and generously undertaken.

The Chairman thought that the Society deserved commendation and congratulation in the matter of the memorial, instead of condemnation, and would have been glad if the same action had been simultaneous throughout all the societies.

Mr. G. Wharton Simpson then read a paper "On Mounting Photographs." See p. 551.

At the conclusion of his paper, Mr. Simpson produced a portfolio of choice photographs, consisting chiefly of the productions of Mudd, Heath, Rejlander, Robinson, Lacy, and others, in illustration of different points in his, which were examined with much interest and admiration by the members.

The Chairman thought that proper attention to the shape, &c., in mounting, was analagous to the exercise of good taste in dress. An artist knew well, that however beautiful might be the person of the model he was about to paint, the result might be entirely spoiled by neglect in the colour and arrangement of drapery; and that the plainest person might, by the exercise of good taste in this respect, be made pleasing and attractive. He thought that Mr. Simpson, in the collection of pictures he had brought—the finest he (the chairman) had ever seen,—in some of the examples he had pointed out, had admirably illustrated this. Regarding the question of shape, he thought it was a pity that there was not some simple and efficient apparatus for cutting the various shapes of that graceful form, the oval, as he had been struck in the various ovals amongst the photographs shown, how few of them had the most graceful proportions. He thought that for many purposes, a kind of paper or card which he had seen, made semi-transparent, and very like horn, might be cut into shapes as guides, more readily than glass. He wished that Mr. Simpson had given a hint or two as to the best remedy for bad mounting, as well as the best means of securing good. He should like to know what were the best means of removing a badly mounted print from the card.

Mr. Simpson said the simplest method of removing a mounted print from the card, was to soak it until the paste or glue were thoroughly softened again. The best way to effect this was to take one or two thicknesses of blotting paper, and after saturating them with water, lay them on the surface of the print for half an hour or an hour. This would generally allow the print to be removed without difficulty. Sometimes a longer time might be required, and sometimes possibly the aid of warm water; but most adhesive materials would eventually yield to continued treatment.

Mr. Howard said he was in the habit of using dextrine for mounting. He had used starch, but found that from the large quantity of moisture it contained, and the consequent expansion of the print, there was always considerable warping and cockling. Dextrine, on the other hand was so very sticky or adhesive with the addition of a very small amount of water, that he found very little difficulty from cockling when it was used. He had found that when the prints had curled, they might be straightened by a very simple process. He just laid the print, face down, on a piece of plate glass, and rubbed it with the ring, or handle of a key, which quickly made it quite flat.

Mr. Wall said that an agate burnisher was the best tool for such a purpose, and was very efficient.

Mr. Valentine Blanchard, referring to the allusion to music, said it must be obvious to every one that a succession of straight or parallel lines would be offensive to the eye, as consecutive thirds or fifths were to the ear. Regarding the question of removing prints from the card, he had found it almost an impossibility, where starch had been used for mounting them. He had soaked a print twelve hours, and then found it tore off in pieces rather than lift entirely away. Referring to the trimming of the prints, he had found, that, contrary to what might perhaps have been expected, plate glass for cutting on did not dull the edge of the knife. He used a knife something like a strong lancet, and found he could cut a hundred pictures without needing to sharpen the knife. On glass too the cut was so clean, leaving no ragged edges. In mounting card pictures he always damped the cards, doing it in a very simple manner. About fifty of the cards were taken by one end, and the other end fanned out by passing the fingers rapidly over, allowing them to pass through the water at the same time. This was the method employed by letter-press printers to damp cards for printing on.

Mr. Wall confirmed Mr. Blanchard's remarks as to the difficulty of removing prints mounted with starch.

Mr. Sebastian Davis had found gelatine the best substance for mounting. He first soaked it for a few minutes in a little water, and then added water at about 200°, which dissolved it into a consistency pleasant for use. He found also that prints mounted so, or with any form of glue, were very easily removed by holding them a few minutes over the steam of boiling water.

Mr. Simpson said that meta-gelatine had been recommended by some for mounting; but he thought its use was not advisable.

The CHAIRMAN said that perhaps where it was found difficult to remove a print from a mount, it might be possible to reverse the operation and remove the mount from the print, referring, in illustration, to a method of transferring engravings to wood, which used to be much practised.

Mr. SIMPSON said that although it might raise a smile to say that the mount might be removed from the print, when the print could not be removed from the mount, it was nevertheless an important practical suggestion. If after soaking well there was danger of tearing the print in removing, the best plan was to lay it down, face undermost, and gently rub away, or tear away, the card in small pieces. This might be done without injuring the print, when otherwise, lifting it, it would have dropped to pieces from the long soaking necessary to soften the adhesive material.

The CHAIRMAN asked if when starch was used the prints would be apt to discolour from iodine, in the presence of sea air.

Mr. SIMPSON said the small amount of starch, and the mode in which it was insulated, would be a sufficient protection. Moreover, starch was used in all the German papers so largely used by photographers, as the sizing material, and if the amount of iodine fell in the atmosphere at the seaside, would affect the one it would the other.

Mr. MARTIN remarked that in order to produce the blue tint on starch it was a necessary condition that the iodine be free and not in combination. The iodine present in the moisture of the atmosphere at the sea-side would generally exist as iodide of sodium. Regarding the removal of prints mounted with starch, perhaps the simplest plan would be to convert the starch into dextrine, which was very easily effected by the aid of acids. If the picture were soaked for a short time in a weak solution of oxalic acid, that would convert the starch into dextrine, which was easily soluble, and the print might readily be removed.

Mr. HOWARD asked what effect that would have on the prints themselves?

Mr. HUGHES said that long soaking alone sometimes made the print so rotten that it was useless when it was unmounted, he was afraid that the addition of acid would not much improve its condition in that respect. Regarding the subject generally, he felt sure that every gentleman present must have been as much interested as himself in the variety of practical hints, so amply illustrated by such a selection of beautiful prints. An opportunity rarely occurred of inspecting such a collection, and he thought he had never heard a paper that was accompanied with such fine illustrations of its various positions, and to persons resident in the country, where the facilities did not exist for getting such things done readily by a professional mounter, the suggestions must be invaluable. Regarding the means of shaping, he felt there was a considerable want, the means of supplying which must, he thought, find a way into commerce soon. He referred to glass guides of a variety of shapes and sizes, to aid the cutting of photographs. The question of proportion of margin was one which would necessarily be regulated very much by individual taste, and also by the purpose for which the pictures were required, and how they were to be kept. For small pictures he was especially fond of great amplitude of margin. One of those exhibited by Mr. Simpson, a child's head, the picture was little more than a ninth size, mounted on a good sized card, which to his taste was charming [the card was 11 by 8, with an india-tint, 5 by 4]. Regarding the material to be used, in that instance, again, the amount of work to be done, and the facilities for doing it would influence the selection largely. He thought that the question might safely be narrowed into one of starch or glue. Starch had many advantages; it was so easily made, and so clean. The difficulty with it was cockling. Glue, on the other hand, largely removed that difficulty. He thought it was always worth while to take a hint from those who did the work professionally, and as Mr. Simpson had just told them, glue was chiefly used by professional mounters. The use of india-rubber had frequently been tried; but, except for scrap-books, it could not, unfortunately, be made available. When used thick it was unmanagable, and when thin it soaked into the print; for attaching prints into scrap-books however, nothing could exceeds its value. A touch at each corner held the print quite flat; there was no cockling; and it could be removed in a moment, without the slightest injury to either the print or book. Mr. Simpson's paper has been so exhaustive, that it really left very little for any one else to say on the subject. He had been in the habit of thinking lately that the entire field of photographic subjects had come under the attention of societies. Here, however, was one of the greatest interest and the utmost importance, which, until to night, had been comparitively untouched, and would furnish material for much subsequent consideration.

Mr. SIMPSON then called the attention of members to several sizes of mounts, with an india-paper tint, stating in answer to several questions, that he had procured them of Mr. Fox, of Little Britain; the prices ranging from two shillings a dozen, upwards. They appeared to him very little more than those without an india tint.

After some further conversation, it was announced that the Experimental Committee would meet at the house of Mr. Hughes, 379, Oxford St., on the last Tuesday evening in November.

Mr. Wormold was unanimously elected a member of the society.

After the usual votes of thanks the proceedings terminated.

PHOTOGRAPHIC SOCIETY OF SCOTLAND.

THE first meeting after the recess was held on the 12th. W. SCOTT ELLIOT, Esq., in the chair.

The minutes of a previous meeting having been read and confirmed, J. Scarth, Esq., A. B. Fleming, Esq., and the Rev. D. J. K. Drummond were ballotted for, and elected as ordinary members of the society.

Mr. T. B. JOHNSTON called the attention of the meeting to an unwarrantable attempt on the part of Lord Abercromby to prevent him placing his camera by the side of a public road, to take a view. His lordship had first objected in person, on the score of danger, the sight of the apparatus having a tendency, he asserted, to excite shying horses. Mr. Johnston having declined to acknowledge his lordship's right to interfere, was next visited by a constable and two other men, who had Lord Abercromby's instructions to order him off. Mr. Johnstom intimated that he would not leave until he was ready, for Lord Abercromby or any one else, and sending his card to his lordship, continued his operations without further interruption.

On the conclusion of Mr. Johnston's remarks, Mr. George Harvey, R.S.A., Sheriff Hallard, and others, expressed their opinions on the very uncalled-for interference which had been attempted, and their satisfaction that it had been so properly resisted. Their observations was fully concurred in by the meeting.

Mr. WALKER, at the request of the Secretary, then gave a description of Mr. Sutton's Panoramic Lens and Camera. Unfortunately, the specimen prints which should have accompanied the camera had not come to hand; but Mr. Walker and other members of the society, who had seen pictures taken by it, bore testimony to their great beauty.

The meeting, as usual on the first evening of the session, concluded with a conversazione. Among other interesting specimens on the table were several prints in photo-lithography, by Mr. Ramage, of Edinburgh, exhibited by Mr. C. Sinclair. The particular process employed was not communicated; but it is expected that the details will be furnished at a subsequent meeting. The specimens exhibited attracted considerable attention.

REGULATIONS OF THE SIXTH ANNUAL EXHIBITION OF THE PHOTOGRAPHIC SOCIETY OF SCOTLAND.

The Sixth Annual Exhibition of the Society will be opened about the middle of December, and will continue open about two months. All descriptions of photographs will be admissible. It is strongly recommended that each picture should be framed and glazed, with a margin of mounting board not exceeding 2½ inches in width. It is also recommended that, in the case of pictures smaller than 9 by 7 inches, four should be in one frame; but no frame must exceed 12 square feet in area.

Each picture must have written distinctly on the back, the name of the subject, the artist and owner, the process (calotype, waxed paper, the different varieties of the collodion process, &c.), and, if for sale, the price. Exhibitors are requested to be careful in specifying the particular process by which their pictures are taken, in order that it may be inserted in the catalogue.

The Society propose to award their silver medal for

The best Portrait or Group.

The best frame containing Six Cartes de Visite; and

The best Photograph of any other kind.

A commission of 10 per cent. will be charged on all sales made during the exhibition.

Works intended for exhibition must be delivered, carriage paid, at the Rooms, No. 90, George Street, Edinburgh, on 30th November next, after which none can be received. A list of the photographs sent must be enclosed in the case, and a duplicate list forwarded by post to the Honorary Secretary. At the close of the Exhibition the pictures will be carefully packed and returned, carriage paid, to the owners.

A. F. Adam, *Hon. Sec.*

9, *South Charlotte Street, Edinburgh, October*, 1861.

Photographic Notes and Queries.

Splitting of the Film.

Sir,—Alkaline hypo, as you suggest, is, I have no doubt, the cause of a "Perplexed Amateur's" difficulty.

A fortnight since I developed *three* collodio-albumen plates; *two* of them, when the development was completed, I placed in a new solution of hypo, the film split into thousands of pieces; I directly dropped a few drops of acetic acid into the dish, and placed the third negative therein, it remained quite sound.

If a "Perplexed Amateur" will test his hypo he will find it alkaline; if he will make it distinctly acid I think his "perplexities" will not trouble him again. I am indebted for the caution — always to acidify a fresh batch of hyposulphite of soda—to Mr. Wardley, of this city.—I am, sir, yours respectfully,

Edwyn Offer.

Manchester, November, 18*th*, 1861.

Dear Sir,—A "Perplexed Amateur" has apparently neglected a precaution requisite in all dry processes, without the plates are gelatinized—that is to gum the edges of the plates. A ready method of doing this, is to lay the plate on a flat surface, and place a straight edge of wood as a guide, and rub the surface to be used for about the one-eighth of an inch all round with a piece of whetstone. By doing this, if the operations are otherwise carefully performed, I am much mistaken if he will not find his troubles at an end on this score; that is, with the proviso that he uses a fitting collodion, the one last-named being simply iodized, needs the addition of a bromide. It should not give a blue opalescent film, but be sufficiently iodized for the film to be thoroughly creamy. Some collodions I have found, although otherwise suitable, had so much alcohol in excess, as to have very little adhesive properties.

Another precaution is, that after the plates are cleaned, they should be well dried at a high temperature. My plan is, to put them in a metal plate box covered over with paper, and placed in the oven of the kitchen-range for a time; let them cool, and use them at once; but previous to coating, rub them over by means of a bit of cotton-wool, with a few drops of old red collodion, finally polish with a chamois.

For Fothergill plates, I have never found this plan fail, but it is not sufficient for the tannin, if the plates are ungelatinized. I have saved some of them from destruction by running a narrow band of spirit-varnish round dry plates previous to soaking. Some operators immerse the plate in the hypo when fixing; a rife cause of loosening the film, from the great specific gravity of the hypo causing it to insinuate itself between the film and the glass.

As a last resource, flooding the plate (after fixing and washing off the fixer) with glycerine and water, equal parts, is often efficacious. There must be some amount of washing after the glycerine, or the plate will not dry.

If all this is insufficient, his case is past prescribing for; although I hope he will state the results.—I am, yours obediently,

M. Willett.

Bristol, Nov. 18*th*, 1861.

Dear Sir,—"A Perplexed Amateur" will find by using one part white of an egg, and *not* more than *two* parts water with ammonia, instead of *one* and *ten*, and flushing it off with *nearly boiling* instead of cold water, he will not be liable to the annoyance he complains of, unless his materials are very unsuitable for dry purposes; and even should this be the case, he may very effectually prevent the film from splitting up and pealing off, by coating *after* fixing, and well washing with a more or less strong "prepared albumen;" if a very desperate case, even the full strength may be used, but generally, much more dilute is sufficient as recommended in my pamphlet. When quite dry, varnish as usual; the albumen will help to strengthen and improve the coating of varnish.

A very strong hypo solution favours the splitting up of film, and plates that have been several times used are more liable to it than fresh ones.—Faithfully, yours,

Alfred Keene.

Sir,—The queries of a "Perplexed Amateur," in your last number, attracted my attention, from the circumstance that about two years since, while using one of the collodions named by him, I was troubled with a similar difficulty. I was using the wet process, the weather being hot at the time, I at first blamed the heat and attribute my difficulty to rapid evaporation of the ether. I soon, however, became satisfied that some other cause was at work; after trying various remedies, I at length applied to the maker of the collodion, but he could not suggest the cause, merely stating that the weather ought not to affect it, as it contained a full proportion of alcohol.

I was obliged to procure a new sample of collodion, when things went well again with me. Some time after, when reading a photographic periodical, I saw it stated that an excess of bromide exerted a mechanical effect on the film, causing it to split or tear: this caused me to think over the circumstances connected with my difficulty, and I remembered that on the occasion mentioned I was working a *new* silver bath, made according to a common formula, but one I never use, namely, by adding a certain quantity of iodide, to throw down iodide of silver, to be afterwards re-dissolved. Now I attribute my difficulty to the fact, that whilst using a *bromo*-iodized collodion, my bath was iodized only, which I believe induced this (mechanical?) action of the bromide; the bath not being very highly charged with iodide, and having no bromide in it, it immediately attacked the bromide in the film. I believe this to be the cause, because I never made a bath in that way before or since, and never met with the difficulty on any other occasion. My usual method of iodizing my bath is the one recommended by Mr. Hockin, viz., by adding a certain portion of collodion to the silver solution, and filtering out insoluble matter. I therefore conclude, that in making a bath, and iodizing by the addition of crystals of an iodide, a fraction of a bromide should be added also.

If you think these remarks worth a space in your valuable journal, they are at your service.—Yours respectfully,

E. E. L.

P.S.—Could ebonite be used for the dark slide and holders of cameras? It appears to possess the requisite qualities, and more so than wood.

[Our correspondent is scarcely logical. First assuming that an excess of bromide would induce a tendency in the film to tear, he then explains that in his case the film being robbed of its bromide by the bath, induced a similar tendency. We have used bromides in all proportions without any such result. For obvious reasons, however, the bath should be saturated with bromide as well as iodide where a bromo-iodized collodion is used. Our own method is simply to place in the new bath a large plate coated with the collodion we use. We fear that ebonité would be scarcely sufficiently rigid for the purpose named; possibly it might be made so. We cannot tell how friction might affect it.—Ed.]

Dear Sir,—Allow me to make a few remarks, which I trust will enable your correspondent, "A Perplexed Amateur," to emerge from his difficulty. I have practised the dry process to a considerable degree, and have often had the mortification of beholding some of the most beautiful negatives "go to pot," in the manner which your correspondent described last week.

I would advise "A Perplexed Amateur" to discard the use of the *collodion*, which he has tried, and use, if possible, an old powdery one. The collodion with which I obtained the finest results, was a mixture of Mawson's, Thomas's, and Hardwich's collodions, together with some of my own making, which I found would not answer for the wet process. These collodions were all about a year old, and unfit for use with the wet process, but by the dry, some of the finest results were obtained.

Regarding the *bath*, I think if "A Perplexed Amateur" gives satisfactory results with wet collodion, there is no fear, if kept in the condition in which it now is, of giving good results by dry. I found out that the greatest cause of the film cracking and peeling off, is *dirty* plates. The necessity of having the glasses *perfectly clean* and dry, cannot be too strongly urged, for I am fully persuaded that if the glasses *are* clean in reality, there need be no peeling off of the film. I have many times spent ten minutes in polishing a plate, and then the glass should be slightly warmed, either before the fire, or by the plan recommended by Mr. Howard, in his paper on the Fothergill process, published in the News some time ago. The film, when drying, contracts, and of course adheres to the plate more firmly in the places where it is most highly polished, and in the parts where it has not been perfectly cleaned, it cannot adhere with sufficient tenacity, and, therefore, cracks and peels off. I have lately been using the wet process by iron development, and intensifying afterwards, when it often happens that the film peels off in the final drying, and if we view the back of the glass by reflected light, we observe that where the film has cracked there is a bright silvery patch, caused by that part being imperfectly clean. Pardon my dwelling so long upon this part of the subject, but I am persuaded that the cleaner the glasses are, the number of cracked and peeled off films will be less.

I think the method of pouring the albumen on to the plate instead of using a bath is best. The proportion of ammonia appears to be very small. I generally use twenty drops to the ounce, whereas your correspondent only uses forty drops to ten ounces of albumen.

In conclusion, if your correspondent uses a suitable collodion, plates *perfectly* clean, and allows the film to set well before immersion, I think he will eventually get rid of his nuisance.—Yours obediently, TEESDALE.

Talk in the Studio.

Photography in a Court of Law.—The Civil Tribunal of the Seine recently decided a case in which M. Edmond, a gentleman of property, was plaintiff, and Disderi and Co., the well known Paris photographers, the defendants. M. Edmond had employed the defendants to take photographs of himself in his barouche with a groom standing at his horse's head, and had paid 100 francs for ten proofs, with the express condition that no other copies should be taken as he did not wish to be exhibited in shop windows or elsewhere. Having ascertained, however, that the defendants sold his photographs to the trade, and that the likenesses were exposed for sale in many establishments, he applied to the tribunal for authority to seize the said photographs wherever he might find them, and for an order to compel the defendants to destroy the negative from which they were printed. As MM. Disderi did not appear to oppose the application, the tribunal at once granted the authority.

Developing without Free Nitrate.—A correspondent referring to our recent paper on this subject says:—"I developed a plate to-day with Mr. Wardley's plan, and was greatly pleased with the results, it is quite a 'lift' for dry-plate photography, and I should imagine useful in wet in certain cases, for instance, in instantaneous views, for it gives the extremity of detail, minus intensity, and then the uniform starting point for thickening the image, will, it seems to me, produce better effects than have hitherto been obtained in this class of pictures."

Award of Medals.—The following award of medals was made at the close of the Photographic Exhibition in connection with the Birmingham Society:—

Silver ...	Portrait	Claudet
Bronze ...	Group	Robinson
Silver ...	Landscape	Bedford
Bronze ...	Landscape	Heath Mudd
Silver ...	Solar, *untouched* ...	Angel, Exeter
Bronze ...	Solar, coloured ...	John Turner Stafford Street, Birmingham

The judges recommended the society to give an *extra bronze* medal to Mr. C. Breese, for his stereographs, and Sir Francis E. Scott generously awards an extra prize to Mr. Rejlander for his works generally, but more especially for the likeness of a little girl (which he exchanged for the one of Prince Albert, which was withdrawn shortly after the exhibition opened), and which was of course too late for competition

To Correspondents.

A.B.C.—On adding the oxide of silver to neutralise a bath, agitation and time are required to produce the effect. If all the oxide you have added be taken up, and the bath is still acid, a further addition is necessary. 2. A twenty-grain solution of iron is generally strong enough for positives, but the strength will be largely governed by the proportion of acid added. In winter the quantity of acid may be considerably reduced. 3. Various strengths of solution, from 5 grains to 50, are used for negative development, with good results. Next week we shall have an article on the subject. During extremely cold weather it is advisable, if possible, to keep the temperature of all solutions up to about 60° Fah. 4. We have not tried the collodion to which you refer, but see no reason why it should not answer for negatives with iron development.

Photo-in-Distress.—Send us a print from a negative, with this irregular granular reduction, and we shall be better able to judge of the cause, and suggest a remedy.

J. T.—The largest size in which we have seen the ebonite baths is 16½ by 12½, the price of which would probably be seventeen or eighteen shillings. Messrs. Silver & Co. will, however, give you the best and most certain information on the subject of size and price. 2. Your question regarding single or double lenses and their prices is not sufficiently explicit. Please put it in a definite form, stating the purpose for which the lens is required.

John Carrol.—We can only suggest that you have not used sufficient heat. A very high temperature is necessary to make copper melt, a full white heat being needed.

An Experimentalist.—Caustic potash is the material recommended by Mr. Hardwich, for cleansing cotton wool prior to its conversion into pyroxyline. The proportions are unimportant; a dilute solution will answer. A common saucepan, if quite clean, may be used for boiling it in. The liquor potassæ of the P. L., usually sold by chemists, contains about 5 per cent. of potash. We have never used the lenses to which you refer, but believe they are pretty good of their class.

J. C.—We do not know certainly of any house which supplies the apparatus with water bath for waxing paper, nor the price; but will make enquiry.

Regnaty.—An old collodion, containing free iodine, is generally best for copying engravings. A portrait lens stopped down, or the triple achromatic lens, will answer best. If a very much reduced copy be required, the full aperture may be used 2. The amount of exposure will be entirely regulated by the condition of the chemicals, the strength of the light, and the aperture and focus of the lens used. 3. Develop with a weak iron solution, with excess of acetic acid, and intensify after fixing, either with bichloride of mercury, or iodine, followed by pyro and silver. 4. Tone with gold and acetate of soda.

N.—The large prints to which you refer, those of M. Alophe, are, we understand, very fine; but they are very much worked up. The touching is, however, done so skillfully as to defy detection almost. Pictures of life-size, or anything near it, if taken direct, must be exaggerated and coarse. To get any approach to delicacy a lens of very long focus, say 60 inches, must be used. In that case, to secure working in anything like the usual time, the full aperture of a lens of 12 inches diameter would be necessary. These are rough suggestions to show how impossible are the conditions on which delicacy depend, when life-size portraits are taken direct. The papers were forwarded to the address indicated.

I. P. E. is thanked for his communication, part of which will be used. We have not yet had time to examine fully the merits of the self-levelling developing stand, but will do so and report shortly. We cannot tell you the fees required for lessons by different photographers; they of course vary. Our own time is at present too fully occupied for tuition. Mr. Dawson, of King's College, is a very able photographer. Apply to him.

An Artist is informed by I. P. E that he can procure the sheet gutta percha he requires, of most respectable chemists.

Black Albumenized Paper.—I. P. E. suggests that paper well blackened with Japan ink, and then albumenized, would answer the purpose of a recent correspondent.

John Martin.—You will find several formulæ for intensifying in the Photographic News Almanac for 1862, which you will receive as soon as it is published. 2. The pistolgraph is altogether unsuited for stereoscopic pictures. The instantaneous stereo lenses of the maker you name are best suited to the purpose. Enlarging from a negative taken on a 1-inch plate up to stereo size would be sad waste of time, and yield a very doubtful result. The last-mentioned firm are not makers of lenses, but dealers. Their stereo lenses may be good of their kind, but certainly not equal to those we have just referred to.

M. B. L.—See a paper and discussion in this week's number on mounting photographs.

F. L. G.—A bath for dry plates should have a little acetic acid added, in preference to nitric acid. 2. Flatted crown glass has generally one side better than the other, which may be easily ascertained on examination.

Ponting.—The small quantity of a bromide which is generally used in a collodion, renders it a matter of comparatively little importance what base is used. Bromide of potassium is very insoluble, and therefore inconvenient. The bromides of cadmium and ammonium are most soluble, and therefore most convenient. If there be, however, already excess of cadmium in the collodion, and any consequent tendency to a thick or gelatinous condition, it is not advisable to use the bromide of that base, as that of ammonium will answer every purpose.

T. A.—We will write shortly, and try to expedite matters.

Teesdale.—We shall be obliged to you for the specimens and paper to which you refer. When a process is vouched by specimens it is always valuable.

W. Bartholomew.—The specimens by Mr. Wyatt which you forwarded are very fine indeed; delicate, brilliant, and artistic. The lighting generally is very good, in some cases a very little extra amount of shadow on one side might be an improvement, but there is nothing to find fault with. A little attention to position on the plate, as suggested in an article on mounting in the present number, might be an improvement. Let Mr. Wyatt try the acetate of soda with his toning bath, and be content to tone slowly. That will largely remedy the slight mealiness (it is not *measles*). We are gratified to find such an ample confirmation of the opinion we have more than once expressed of the lens in question. Nothing could be sharper or better defined than these. The pattern on the carpet would be better if less defined.

Some Critical Notices and other articles, as well as several correspondents in our next.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 169.—*November* 29, 1861.

IN MEMORIAM.

It is with no ordinary feelings of regret that we announce the death of Mr. W. G. Lacy, of Ryde. The victim for many months, unconsciously, of an incurable malady, which he regarded as but the debility consequent upon over-exertion, he came up to London a few weeks ago, at the termination of a season unusually exacting in its demands upon his labours, for rest and medical advice; his symptons, which had remained in abeyance during the excitement of actual duties, rapidly assumed a serious aspect, and terminated in death on the night of Thursday, the 21st instant.

In him the photographic world has lost one of its ablest artists. During a comparatively short professional career he rapidly rose into the first ranks, where he found few to equal, none to surpass him in his speciality—portraiture. Not more than five years ago, he was entirely unacquainted with photography, and was engaged at that time in producing crayon portraits. The capabilities of photography being brought under his attention, he at once devoted himself heart and soul to its study and practice, especially regarding it as a means of artistic expression. He soon addressed himself to the professional practice of the art, and pursued it with an unobtrusive ardour which steadily secured both artistic and commercial success. His first efforts were confined to the production of glass positives. About three years ago, a collodion portrait of a child was brought under our attention, as the production of an unknown provincial photographer. Its high artistic merit at once arrested our attention, and we procured leave to copy it. The pose, arrangement, and expression, all marked the work of no common mind. We have since learnt from himself that the picture was his: any merit it possessed he modestly attributed to the model, a sweet little girl he had seen in the street, and at once exclaimed to himself, "That surely is the embodiment of the principal figure in Millais' 'Autumn Leaves.'" He obtained permission from her parents to produce a portrait of the youthful model, and we saw one of the results.

Vignette portraiture, with the productions of Mr. T. R. Williams as his standard of excellence, next engaged his attention, and these he produced with a perfection scarcely if at all, inferior to those of the master whose works were his ideal. It was, however, in album portraits, or *cartes de visite*, his especial superiority lay. There we consider him unrivalled. The exquisite delicacy of definition and texture, the perfect balance of lines, and of chiaroscura, the ever-varying, and always graceful arrangement of pose and accessories, the admirable and characteristic grouping which his card pictures present, all combine to render them the finest studies of composition which we have ever had the satisfaction of seeing in photographic portraiture.

About twelve months ago his album portraits first came under our notice, and from their uncommon merits attracted our attention. In answer to our inquiries he readily explained his method of working, an account of which we published in an early number of the present volume. Much of the beauty and delicacy of his pictures he attributed to the process he used. We have, however, always attributed it more to the fine taste, and artistic skill of the man; an exquisite perception of the effect of light on his model; a fine appreciation of the pictorial effect to be produced by actual objects; an almost intuitive sense of the amount of pictorial gradation, which every stage of development would give, were amongst his distinguishing characteristics. Since our introduction to him twelve months ago, we have had abundant opportunities of examining his productions, of seeing him operate, and tracing consequences to causes, and we speak with confidence of the sources of success.

Since our readers have been familiar with his name, his success in achieving connection and position has been as complete as it has been in an artistic sense. Commissions from the *élite* of society both in position and taste, have crowded upon him. The patronage and highest expressions of the approval of royalty at home and abroad, have crowned his efforts. The last portraits he took were those of the Grand Duke and Grand Duchess of Russia and the Princess Olga. He dies, alas, when he has attained the topmost pinnacle of success.

Such success is not attained without commensurate effort. Our departed friend was an earnest art student, and an indefatigable searcher after all knowledge which could advance him in the pursuit of his favourite art. With opportunities more limited than many, he had acquired a highly cultivated mind. No effort was spared to acquire the most perfect knowledge and the highest skill: no expense was spared to secure the most perfect appliances. In answer to a question we put regarding a toning formula for which he had recently paid £20 to a French artist, when we enquired was it worth it, he answered, "In aiming at perfection a very slight step is a great deal, and is worth anything." Such an answer was a key to his success. The slightest step was regarded as worth the greatest effort. There is alas, another point of view from which to regard his efforts, which, we fear, overtasked nature, and aided, if they did not cause, his death at the age of thirty-three. We cannot moralise, however, with our friend scarcely yet coffined. Our readers will bear with us if our own familiarity with skill and worth only just beginning to attract public attention, has induced us to extend this notice beyond a brief obituary paragraph. Those who have seen his productions will readily enter into all we have said.

PHOTOGRAPHY ON WAXED PAPER.*

Development.

In the preceding operations dishes of gutta percha may be used, but for the following we must adopt those of glass or porcelain.

For each sheet measuring 45 by 55 centimetres (18×22 inches), take a litre (35¼ fluid ounces) of saturated solution of gallic acid to which, at the moment of employing it, add 150 grains of solution of aceto-nitrate of silver, which has not been employed for sensitizing. The side of the paper which has been exposed to the light is placed downwards on the bath of this solution, taking care to avoid the formation of air-bubbles, and then completely immersed by the aid of a soft brush, which must be kept perfectly clean and used for no other purpose. The image, at first invisible, will appear in about five minutes; if the exposure has been well timed, the parts which should become black appear red, gradually becoming darker and darker until they are brown black; the half tones will begin to appear only when the shadows and dark portions are sufficiently intense.

If the exposure has been too long, the half tones will appear at the same time as the dark parts of the image, and appear so strong as to destroy all contrast; the darks will continue red and transparent even when nitrate of silver be added, and at last the whole picture will become darkened

* Continued from p. 554.

all over. If, on the contrary, the picture commences by appearing of a gray colour, it may be at once reckoned among the spoilt proofs; only the deepest shadows will come out, we may be sure that the exposure has been too short, or rather that the proof lacks excess of silver from not remaining long enough upon the silver bath, or in the latter being too weak. It sometimes happens that the paper turns brown in the gallic acid solution, and the image will scarcely appear; this is due to the bad quality of the paper and occurs only too frequently.

A good proof increases in strength very gradually, and remains stationary when all the silver of the gallic acid is deposited upon the paper. This affords facility for putting the proofs in the developing solution at night to find them finished in the morning. When a proof does not increase in strength we must add a little more nitrate solution, say 15 grains at a time, at intervals, not so quickly; for if the nitrate has not sufficient time allowed it to deposit itself upon the negative, it becomes precipitated, and thickens the solution of gallic acid, which then communicates a dirty yellow hue to the white paper. If one part of the picture is slower than the others in developing, or rather, if the distances are not black enough, which would cause the positives to be deficient in aërial perspective. The defect may be easily remedied by spreading a little aceto-nitrate of silver over the spot by means of a tuft of cotton wool, and then passing the gallic acid over it. The solution also becomes very thick when the negative has not been sufficiently exposed; for the silver not being sufficiently attracted to certain parts of the picture, is deposited over the whole surface, and is rendered opaque by a deposit of oxide of silver.

At the conclusion of the development, the gallic acid will always be found to assume a brown colour from excess of nitrate of silver no longer necessary to the formation of the image; the latter being completed, the paper is removed from the solution and then immersed in a dish filled with water. I prefer to make the negative more intense, than it is required to be finally to produce positives, and I watch for the moment when the image, viewed by reflected light, has lost its detail, and appears almost entirely black, while viewed as a transparency all the finish of a good drawing is visible. The negative will always appear more vigorous than it really is while impregnated with the brown gallic acid solution; in the washing bath, and when the back of the proof is rubbed with a tuft of cotton to remove the silver deposited there, especially when the development has continued a long time, the proof will soon begin to appear weaker, and it will lose more of its intensity in the succeeding operations—fixing in hypo, and the final waxing of the paper.

Fixing.

After the proofs have been left at least half an hour in water, twice renewed, they are dried between folds of blotting-paper, or suspended on a line covered with blotting-paper.

The proofs are now insensible to diffused light, but to render them permanent in a strong light and in sunshine, all the unchanged iodide of silver must be removed from the paper by means of a solution of hyposulphite of soda of the strength of part of this salt dissolved in three parts of rain or river water. Gutta percha dishes are preferable for hyposulphite of soda, which strongly acts upon the glaze of porcelain dishes, and dissolves the marine glue and varnish of glass dishes when constructed of pieces cemented together. Only one negative at a time must be put into the hypo solution, and left in it until its yellow colour has quite disappeared, and consequently the iodide of silver dissolved, which will require from half to three-quarters of an hour. The negative is then washed freely in abundance of water, and then placed in a vessel of water, frequently changed, for ten or twelve hours; it is then dried between sheets of blotting-paper. In this state the negative will remain permanent, but it will have lost its transparency, and appear granulated after being dried. To remedy these two defects, it will be necessary to revivify the wax by passing a warm flat-iron over the negative, or what is still better, re-waxing it. With turpentine waxed paper it is quite indispensable to give this last waxing, in order to protect the negative from spots while taking positives from them. If after this second waxing, which renders the proof transparent, any yellow spots of iodide of silver remain, the proof must be returned to the hypo bath and treated as before.

The sky in vigorous negatives is seldom sufficiently opaque to oppose the presence of light; in this case a wash of Indian ink may be applied.—(*Le Moniteur de la Photographie.*)

Scientific Gossip.

The preparation of pure materials for photographic purposes is a subject to which our readers are aware we have frequently called their attention. We have been induced to do this for the reason that more than three-fourths of the failures which have come under our notice (our own included, of which we have a most instructive number*), have been readily traced to a chemical impurity in some of the materials employed; and, moreover, it is our firm conviction that the future triumphs of photography will be gained far more by attention to the purity of the various chemicals used than by any mere manipulative excellence. The great stumbling block of photographers has been, and doubtless will be for a long time, until they are content to pay far more than its present price for it, the nitrate of silver which they use. Let those of our readers who are inclined to question our correctness, when we assure them that this salt has scarcely ever been obtained in a state of absolute purity, and that a manufacturer would scarcely be repaid for his time, expense, and trouble in making it, even were he to charge twenty shillings an ounce—let such read the difficulties which M. Stas had to overcome in the endeavours to obtain metallic silver fit for his experiments.

The first process which was tried was the reduction of chloride of silver to the metallic state. This is an operation which is not unfrequently performed by the photographer; but, unless important modifications are introduced into the processes usually adopted, it will be impossible to obtain the metal in a state of even approximate purity. All the processes hitherto made known for the reduction of chloride of silver yield a metal containing silicium, copper, and iron. In order to obtain it free from the last two metals it is necessary to pour the nitrate of silver, diluted with thirty times its weight of water, into a slight excess of pure hydrochloric acid, and then to wash the precipitate with cold distilled water. The chloride is afterwards to be dried at the ordinary temperature, and digested, after being finely powdered, in nitro-hydrochloric acid. When well washed after this treatment the chloride does not retain the slightest trace of either copper or iron, whilst so long as it remains in a curdy form it retains in its pores, like coagulated albumen, some of the bodies which were dissolved in the liquid from which it was precipitated. When, however, dried at the ordinary temperature and finely powdered, chloride of silver very easily yields to aqua regia the foreign metals with which it is contaminated. When thus purified the chloride of silver must not be reduced by Gay-Lussac's method (fusion with chalk and charcoal), or it will be certain to be contaminated with silicium. It must be mixed with its own weight of pure dry carbonate of soda, containing a tenth part of pure nitrate of potash, and heated in a crucible of white unglazed porcelain, a small portion being introduced at a time, and the heat carefully regulated to avoid the bubbling up of the mixture. A few precautions are necessary in reducing the silver in this way. The unglazed porcelain crucible must be placed inside a clay crucible, and the space between the two crucibles filled up with calcined pipe-clay, powdered and mixed with 5 per cent. of fused and powdered borax. Under the influence of heat the borax fuses and solders the whole

* "A good failure is often more instructive than success."—Faraday.

together. When the chloride of silver is reduced the whole can be handled, and the melted silver poured out as if from one crucible; the great bulk of material through which the heat has to pass before it reaches the porcelain crucible prevents any danger of loss of silver owing to the cracking of the former. After the chloride is reduced it must be re-fused with a tenth of its weight of pure nitre and borax, and then run into an ingot mould lined with pipeclay. In this manner bars of silver are obtained which contain scarcely appreciable traces of foreign matters.

Another plan of preparing metallic silver, which yields it of perhaps greater purity than the foregoing is one proposed by Baron Liebig. The process consists in reducing in the cold by means of pure milk sugar, a pure concentrated ammoniacal solution of nitrate of silver, to which pure potash has been added until fulminating silver begins to precipitate. After a short time a violet precipitate is formed, which is transformed into a mirror of silver if the solution does not contain more than 10 per cent. of nitrate. If on the contrary it contains much more metal, the violet precipitate of silver remains. This precipitate after being washed with water is digested in aqueous solution of ammonia, which removes all the copper, if the silver contained any. When dried, it preserves its violet colour, and evidently constitutes one of the peculiar states of silver referred to by Mr. Malone, during his lecture on the photographic image recently published in our columns. Heated to 300° or 350° C., the metal becomes incandescent, and then assumes its proper colour, being of a dead white. To reduce it into bars, it is fused with a certain quantity of pure nitre and borax, and run into the lined ingot mould as above mentioned.

One difficulty in these experiments was to know when the silver was really pure, as there existed no standard wherewith to compare the different specimens. After many trials, M. Stas at length succeeded in preparing some absolutely pure silver by the electrolysis of argento-cyanide of potassium; the deposit being made upon a surface of porcelain previously covered with a mirror of silver by Liebig's method. For the positive electrode coke was used, obtained by heating the vapour of naptha to redness. To obtain the nitrate of silver fit to prepare the cyanide from, some of the purest silver obtainable was dissolved in nitric acid, evaporated to dryness, and the salt fused. After cooling it was powdered and digested in cold water, care being taken, however, to leave some nitrate of silver in excess undissolved in order to prevent the oxide of copper from entering into solution. The liquid was then allowed to stand for three or four days, filtered through double filtering paper, then digested with an excess of oxide of silver, and allowed to remain at rest for a sufficient time. This solution was diluted with water until it only contained a thirtieth part of its weight of nitrate, and poured into pure aqueous hydrocyanic acid, until cyanide was no longer precipitated. The cyanide was shaken in the liquid to finely divide it, and then washed with water acidulated with nitric acid, and finally with pure water. It was then diffused through an amount of aqueous hydrocyanic acid equal to that used in its precipitation, and then pure ammonia or potash was added to the mixture till the precipitate was all dissolved. When undergoing electrolysis, the positive pole of carbon was surrounded by cyanide of silver contained in a little linen bag purified by washing in hydrochloric acid; in this way silver was returned to the liquid as fast as it was lost by electrolysation. M. Stas says, that he has been unable to find any foreign body in this silver after it has been fused in an unglazed porcelain crucible with a mixture of purified nitre and borax.

Another plan by which very pure silver may be obtained is, by making use of the reaction between finely divided phosphorus, and a 1-per cent. solution of nitrate of silver. This process is very slow, but the metal, after having remained for a long time in an excess of a solution of nitrate of silver, and then being digested in ammoniacal water, yields, after fusion with purified nitre and borax, *absolutely pure silver*. M. Stas states that by this reaction he prepared the first really pure silver that he ever possessed.

One of the most interesting results obtained in these experiments is the plan for ascertaining the purity of silver. When the metal is absolutely pure it will remain melted in the air at a sufficiently high temperature to volatilize it, without becoming covered with any scum or discolouration, and without giving a coloured vapour. Silver containing no more than the 1-500,000th part of iron, copper, or silicium, becomes coated with a very thick and mobile scum when it is fused before the air and gas blowpipe. Silver containing scarcely appreciable traces of copper, when volatilizing in an oxidizing flame, always gives a coloured vapour. This assay may be performed on charcoal or white burned pipe-clay, or on porcelain. The scoria derived from the impurities in the metal always forms upon the surface of the flattened spheroid resulting from the fusion. After cooling, the foreign matter is found adhering to the silver, near the point of contact of the metal with the support.

THE INFLUENCE OF HEAT ON THE BATH AND DEVELOPER.

BY J. C. LEAKE, JUN.

Sir,—I have recently conducted a few experiments with a view of ascertaining how far the sensitiveness of the film of bromo-iodide of silver is affected by temperature; and as at this period of the year the subject may possess some interest, I beg to submit to your readers an account of my experiments.

It seems to be accepted as a fact among photographers that a reduction of heat is followed, as a matter of course, by a diminution of sensitiveness, and *vice versa;* it is also said, "*All* chemical action is accelerated by heat." Now the following experiments tend to show that this statement must be taken with a reservation; but as I may have fallen into some error, they shall be detailed, and if some other experimentalist will repeat the operations and report the result, we may arrive at some satisfactory conclusion.

In all the experiments, a bromo-iodized collodion, made on Hardwich's formula, was used, and a bath containing forty grains of nitrate of silver to the ounce, with two drops of nitric acid, to twenty ounces of solution.

For the first experiment, the bath was placed in the open air during the recent frost, till the temperature was reduced to about thirty-five degrees. A plate excited in this, was exposed in the camera twenty seconds. This was quite long enough and produced a fair picture; but the formation of the iodide of silver was very slow, (it was at least five minutes before the plate was fit for the camera) and the development though regular, was somewhat tardy.

The bath was now warmed up to fifty degrees. The iodide of silver then formed rapidly, and the film was ready for the camera in about three minutes. An exposure of fifteen seconds produced an impression much resembling that of the first experiments, but manifestly the other five seconds exposure would have been an improvement. In this case the development was more rapid, and the appearance of the image altogether more satisfactory.

On heating the bath to eighty degrees, the iodide was most rapidly formed, and the plate was ready for the camera in about two minutes. After an exposure of fifteen seconds, on application of the developer, the high lights started out instantly, but the half-tints held back for a longer period than before, and the plate was fogged to an extent which rendered it useless.

On cooling the bath to the ordinary temperature it again worked well, and appeared none the worse for the treatment it had received. In all these experiments an iron developer, forty grains to the ounce, had been employed, and had been used cold.

I now resolved to try the effect of heat in the developing process, the bath remaining at the temperature of the room (about sixty-five). A plate was excited, exposed twenty seconds, and developed with some of the same solution as before, but with the temperature reduced to about thirty-five degrees.

The development was very slow, the image was weak, and when fixed was covered with minute spangles of metallic silver, the whole effect being that of under exposure.

The solution was now warmed up to fifty degrees. A plate exposed the same time as the last, developed perfectly, with plenty of detail, fair intensity, and clear shadows. On raising the temperature to one hundred degrees the image started out instantly, but the half tints were not so perfect as in the former experiment, and the whole plate was slightly fogged. On repeating this experiment, I added a small additional quantity of acetic acid to the developing solution; this prevented the fogging, but I do not think any advantage resulted from raising the temperature above—say, seventy degrees. From the experiments above detailed, and many others not mentioned here, I am inclined to the belief that in the wet process the most harmonious pictures will be produced when all the solutions are at an even temperature of about sixty degrees, and that no increase of sensitiveness, or any other advantage will be gained by heating either bath, or developing solution, or both, above that point.

THE FOTHERGILL PROCESS; ITS PRACTICE IN TROPICAL AND TEMPERATE CLIMATES.

BY JOHN TAWSE, ESQ. OF MADRAS.*

The object of the writer is to adduce the photographic experience of several years in a tropical climate in support of the beautiful process known as "Fothergill's." The photographic art is now so widely practised in India and in the Colonies, that any reliable practical information on a really good dry process suited to those climates is of value, as saving much disappointment to tourists who may wish to bring from the scenes of their travel first-class photographic delineations of what most interested them. Many of the published processes for imparting keeping-qualities to collodion plates, however well they may be suited to the climate of England, are found to be insensitive and unmanageable in the red hazy glare of tropical light, besides being liable to faults inseparable from the chemical effects of excessive heat. On this account wet-collodion photography has hitherto been chiefly practised in the East, which necessitates either a dark tent for migratory work, or a cumbersome photographic van, for the preparation of the plates. Besides the many preservative agents known in this country, the writer has experimented with gum dammar, the juice of the sugar-cane (which contains a large per-centage of mucilage), tincture of opium, oxymel of squill, decoction of linseed, and many others, all of which are capable of exercising a certain preservative influence when in contact with iodine of silver on the collodion plate, but have all more or less the fault of producing stains in the development. In the case of the oxymel of squill—a compound totally different from the simple oxymel—the objects on a plate so under-exposed as to be of the positive character appeared in hues very much resembling the natural colours; the light green of the tamarind leaves was plainly perceptible: but the substance, as at present prepared, is valueless for photographic purposes on account of the stains it produces. The tincture of opium has also a very peculiar effect upon the collodion film; but in India this important drug is rarely to be procured uncontaminated with fusel oil, owing to the exclusive use of methylated spirit in its manufacture. An aqueous decoction of opium was unsuccessful from the large amount of adulteration in the Indian drug. The narcotine not being soluble in water, the full properties of opium as a preservative agent could not be availed of in this form. The preservative effects of the simple oxymel in the climate of India will be noticed hereafter.

The theory and manipulation of the Fothergill process, as practised in this country, are well understood. The immediate object of the writer is to detail practical differences in the mode of working and chemical action peculiar to operations conducted in a high temperature and in an atmosphere remarkable for hygrometric changes.

The electrical state of the atmosphere, as well as its condition with reference to its proportion of ozone, has been too much overlooked in the phenomena of the photographic action of light. It is highly probable that the latter agent plays a very important part in the chemical changes which are often so incomprehensible, when any known condition varies in the photographic art. It is well known that ozone affects the colour of strips of bibulous paper soaked in a solution of iodide of potassium and suspended in the open air. Iodine in this form is, in fact, a very delicate test for the presence of ozone in the atmosphere. Is it not probable therefore that its effects are also apparent, although not understood, in the iodide of silver in the collodion film?

The electrical state of the atmosphere in India has a marked effect upon certain chemical combinations. The casein of milk is precipitated when the atmosphere is highly charged. The writer has noticed these effects in a marked degree in the hot season of a tropical climate, and has known a severe thunder-storm to render useless a nitrate of silver bath which was previously in good order, and which, from the care taken of it, could not have suffered injury from ordinary chemical causes. These influences are supposed by the writer to affect the working of some of the dry processes in India—those at least which produce good results in this country, and fail in the East, even in practised hands. The modifications of the Fothergill process, hereafter described, are no doubt rendered necessary by similarly occult causes, quite apart from simple increase of temperature.

On Cameras and Lenses.—Before commencing the more immediate subject of these remarks, it may not be out of place to consider the description of camera suited to operations within the tropics; also the most correct and convenient form and size of lens for landscape work, which is, of course, all that the dry processes are adapted for. Photographic tourists in this country mostly prefer the portable camera, made with a folding-in flexible body, so as to admit of being packed in a very small space. For warm climates, however, the solid form, made of well-seasoned Spanish mahogany, is by far the most serviceable and satisfactory. To protect the focussing screen, the bottom part, upon which the inside body of the camera slides, should be made to fold up on hinges, by which means it becomes a solid box closed on all sides. When the bottom part is down for use it is supported by two sliding panels of mahogany, which draw in and out as required. A handle on the top of the camera completes its portability.

The bellows form of camera, besides being unsteady when exposed to wind, is very apt to become eaten by insects; and another serious objection to it is, that for landscape photography it is very difficult to preserve the slide or plate-holder in a position at right angles to the axes of the lens. In countries where labour is cheap and plentiful, the one is just as easily carried as the other, and the solid form, if well made of seasoned wood and brass-bound, will last with even hard usage for years. Rack-and-pinion work on the camera itself, for focussing, is more convenient with long-focus lenses than the handle and universal joint fitted on the lens-tube. The best form of stand is the common tripod with triangular top to permit of the camera moving in azimuth. If well and strongly made, these stands are remarkably steady even in windy weather.

The size of the lens must, of course, be suited to the description of work intended. For ordinary plates, viz. 10×8 or up to 12×14, a Ross's 4-inch view-lens gives fine results, as these sizes are considerably within its powers.

In dry processes where a long exposure is needed, a long-focus lens gives better half-tones than a lens of a shorter focus where the rays impinge upon the plate at a greater angle.

The orthographic and triplet lenses have not as yet found much favour in the East. Their chief advantage is the absence of distortion. But in working the above-sized plates with a Ross's 4-inch lens, the distortion is so small in an ordinary landscape that it is not perceptible, and for fine definition and rotundity nothing seems to equal it.

Gutta-percha baths should never be used in a tropical temperature.

Details of Manipulation.

The collodion best suited to the Fothergill process is one that gives a tolerably compact film—not too contractile, as in this case there is always a tendency to curling up and peeling off at the corners and edges of the plate. The iodizer should be in sufficient proportion to give a dense creamy film. A blue opaline film will not answer in any process where the surface

* From the *Photographic Journal.*

nitrate of silver is wholly or partially washed off. The collodion found to answer better than any other in high temperatures is that made expressly for this process by Mr. Keene, of Leamington. Next in quality comes Hockin's negative collodion in hermetically sealed tubes. The latter, however, has frequently been found ozonized, although carefully unpacked in the dark, in which state it still yields good pictures, although extremely insensitive to light. It is of the greatest importance in working with collodion in tropical countries, whether plain or iodized, never to expose it to the light, as the high temperature is peculiarly apt, in conjunction with light, to cause the ether to become acid, in which state the collodion discolours immediately on being iodized.

Whatever kind of collodion is used, better tones are always obtained by keeping it iodized for a few days before use. It is a mistake to suppose that in a high atmospheric temperature there is any difficulty in coating even large plates with collodion, owing to the rapid evaporation of the ether and alcohol. The writer has not found this to be the case, even with plates 18×24, at a temperature from 90° to 100° F. Some collodions become glutinous; but this is easily rectified by adding to each ounce 2 minims of pure chloroform.

Coat the plate in the usual manner, and allow the collodion to set firmly before dipping in the bath. Wash up and down as usual, and allow the full time of immersion, viz., two minutes with the thermometer between 75° and 95°, three minutes at 60° to 70°, four minutes at 60° and under. The iodide of silver will not be perfectly formed under two minutes, even at a temperature of 90°. This the writer has ascertained from numerous trials.

Wipe the back of the plate carefully with a piece of clean rag, on the removal of the plate from the bath, to remove drops, and also to give time for the surface to drain off its surplus nitrate of silver. Place the plate on a stand perfectly level, and pour carefully over it distilled water in proportion as under:—

16 drachms for a plate	... .	8 × 10
20 " "	... ...	12 × 15;

pour gently from a 2 oz. or 4 oz. phial, advancing the wave gradually until the right quantity of water is upon the plate. The stand should be placed in the middle of an ordinary developing dish. Take hold of the ends of this dish with both hands, and oscillate in such a manner as will cause the water to flow in a wave backwards and forwards without spilling (this is easily done with a little practice); continue this washing to equalize the bath solution on the surface of the plate for two minutes, then pour off and drain for a few seconds.

The albumen solution is made as follows:—

White of fresh eggs	6 oz.
Distilled water	6 oz. to 8 oz.
Chloride of ammonium	6 grains.

Shake in a large bottle until well frothed, and filter through blotting-paper.

Pour this solution carefully on the plate in the same manner as the water, wave backwards and forwards as before, and allow it to rest upon the film for four minutes, the object of this being to form a perfect layer of albuminate of silver combined with chloride. Pour off and drain freely. Then immerse the plate in a flat bath of distilled water, wash well in this so as to remove all the surplus albumen. The water should be deep, so as to flow freely over the surface of the plate. The plate is then to be reared up to dry spontaneously, resting on blotting-paper, and leaning against glass.

In the ordinary way of working, the plate is now complete for exposure; but in the East, or any country where there is a red hazy atmosphere from excessive heat, the clearness of development and intensity are greatly increased by pouring over the plate, after the last washing, a solution made as follows:—

Common Indian gall-nuts, commonly called Myrabolams, in powder ...	... 2 drachms,
Boiling distilled water	... 8 oz.;

filter, and use when cold.

The writer cannot explain the chemical action of the gall-nuts, except that they contain gallic acid, and probably tannin. It is sometimes difficult to obtain sufficient intensity in some states of a tropical atmosphere. The above solution is found to produce great intensity, combined with clear definition in the distance, and absence of solarization. The development is also much accelerated.

The developing solution for this process, with or without the above modification, is made as follows:—

Pyrogallic acid	10 grains
Distilled water	10 ounces
Glacial acetic acid	200 minims.
In a separate bottle, mix—	
Nitrate of silver	60 grains
Distilled water	2 ounces
Citric acid	10 grains

Dissolve.

The exposure in India, with a Ross's 4-inch landscape lens and ½-in. diaphragm, is from 8 to 12 minutes. The plate must not be under-exposed, but a little over; viz., from 3 to 5 minutes makes little difference, except that the development is more rapid and the shadows better defined.

Fothergill plates, prepared as above, are exceedingly hard and firm in the film, and cannot be injured by any amount of washing; neither has the film the least tendency to peel off the glass, if the edges are roughened in the usual manner.

To develop, first dip the plate in distilled water (the same as last used will do) so as to moisten the surface, then place it on a levelling stand, and pour over it the requisite quantity of pyrogallic solution to which has been added 15 or 20 drops of silver solution with citric acid. Wave backwards and forwards as before. The picture appears in a minute or two. The developer, as above made, never becomes turbid, and the development is clear and uniform. The combination of citric and acetic acid is better than using either alone. Care is required not to over-develop. The intensity should be judged of by the details of the picture, and not so much by the sky as is usually done. Wash well before fixing, and fix with hyposulphite, not cyanide. Dry and varnish as usual.

The plate will keep for many months, even during the rains and in damp situations.

If stains are encountered they are generally on the surface, and can be rubbed off with a piece of cotton. This is almost invariably the fault of the bath. For any dry process in a hot country the best form of bath is the simple solution of silver, saturated with the iodide as usual, without any alcohol or ether. With pure recrystallized silver, the writer has never either acidified or neutralized. A bath prepared as above is always in good order if kept in a dark place. The strength should never fall under 35 grains of silver to the ounce. It is better to fill up with a solution of 40 grains of silver in distilled water, without any iodide, as the bath in India has a tendency to become charged with an excess of iodide of silver in a reduced form—a condition which some have termed supersaturation. This is a fertile source of stains on the surface of the plate.

In the event of breaking the glasses of a yellow lantern or a focussing screen where such cannot be replaced, it is useful to know that glasses coated with iodized collodion, sensitized, washed and dried, answer the same purpose.

Critical Notices.

PHOTOGRAPHS OF SCENES IN PERTHSHIRE, ON THE THAMES, &c. By Vernon Heath.

We have recently had an opportunity of inspecting a series of photographs of Highland and other scenery by Mr. Heath, some of which were, we believe, a commission for Her Majesty the Queen. It has rarely been our duty to examine a series of pictures so replete with all which constitutes good photography and good art. The scenery depicted abounds with those features which are at once the charm and the difficulty of photography—foliage and water. To render either of these properly requires the highest skill and judgment, whilst to combine the two perfectly is the height of photographic success. In the pictures before us the success is complete in this respect. Almost every scene combines more or less of these features, but we may mention a view "On the Banks of the Earn," one "On the Banks of the Almond," an "Old Mill on the Almond," and a "Bridge over the Almond," as very perfect examples: foliage the most crisp and detailed, water bright, transparent and full of motion. A "Burn—St. Fillans," is one of the most charming bits of rock scenery and falling water we have ever seen. In all these there is the greatest brilliancy combined with most exquisite delicacy; great vigour and relief combined with the most perfect atmospheric gradation. Too often in photography, when a picture has been praised for vigour it has suggested hardness; when praised for softness it has been suggestive of lack of brilliancy: or, if the photographic characteristics were perfect, and it was praised for these, a suspicion of the absence of artistic elements has been created in the mind. Here, however, all the highest photographic qualities are united to a fine artistic feeling. In this respect we may especially refer to "A Peasant's Cottage." Here, amid characteristic scenery we have an old rustic Highland cottage: to give this value and life an old woman with her wheel sits in front of the door. "A happy accident," some one exclaims, looking at the picture; "I never have the good luck to meet with such characteristic figures in my landscape work." Such a person would stare when told that the cottage was found in one spot and the old woman in another, and that Mr. Heath took the old woman and her wheel several miles in a carriage in order to give life and keeping to the picture.

Judicious lighting is one of the great charms in each picture, and secures brilliancy and relief in the highest degree.

Two views on the Thames, near Maidenhead, are exquisite photographs. If it had been a matter under control something might have been desired in the composition notwithstanding that there are many elements of the picturesque. But the photography here, is perfect. A white cottage, green foliage, water, and black lock-gates are all rendered with perfect justice and fine effect. There are no white skies, a graduated tint or a natural sky being present in each picture. The printing of Mr. Heath's pictures is the finest we are in habit of seeing.

In all cases a bromo-iodized collodion and iron development was used. Mr. Heath has promised to give a brief account of his exact formulæ and manipulations for the benefit of our readers, who will doubtless look for it with interest.

A SERIES OF CABINET SIZE PHOTOGRAPHS OF PLACES OF HISTORICAL INTEREST IN ENGLAND AND SCOTLAND. By S. Thompson. A. W. Bennett.

This series consists of fifty pictures, and includes great variety of subject, most of the scenes from their own picturesque character or from historical association being full of interest. Few places, for instance, have so many charms of their own, combined with so many associations to add value to those charms, as some of the pictures which form a "Waverley Series" in this collection; the varied views of Abbotsford, Melrose, and Dryburgh, constituting, as Mr. Thompson phrases it, "the home, the favourite haunt, and the last resting-place of the Minstrel of the North." Here is the tomb of the bard, novelist, and historian, within the ruins of Dryburgh. It is one of the pictures which pleases us best. Mr. Thompson has been embued with the sentiment of the place, and has embodied much poetry in this photograph. We must confess we should not have admired a brilliant sparkling piece of photography here: we have, instead, a picture full of tender solemn repose; low in tone, but with fine, although sombre chiaroscura. We would suggest but one alteration, which can easily be made in printing: in vignetting such a subject the form of the gothic arch should not be repeated at the base, or, if done at all, care should be taken to make the repetition less regular.

A series of views of Oxford, contains some of the best pictures. A view of the High Street is very fine, the point of view well chosen, the composition good, and the atmospheric effect very fine. A view of the High Street and Queen's College is another good picture. "The Martyr's Memorial" is also a good composition. It is a little defaced by the spectral figure of a man, who has planted himself in the foreground exactly in front of the middle of the erection, and through whose unsubstantial body the railings which surround, and the steps which lead up to the monument, are clearly visible.

A "Series of Reproductions" contains copies of some very choice engravings, very carefully and skilfully executed, rendering with great delicacy all that is in the originals.

All the pictures we have examined are carefully executed: many of them are very fine, and exhibit judgment and taste. There are, however, one or two very palpable faults in some of them, which it would be unfair not to allude to. The first is the exceedingly unsuitable light in which some of the negatives have been taken, which gives a flat, tame, picture, without either brilliancy or relief; the manipulation is careful, the definition good, and all but the lighting is satisfactory. Another fault is in the mode of vignetting some of the prints, in which a hard abrupt line is manifest, where imperceptible gradation should have been present. We point out these faults for future avoidance, and do not wish to be understood as referring to nearly all; as many of the series comprise choice subjects, fine composition, and good photography.

PAINTED BACKGROUNDS, SET-SCENES, AND PROFILE ACCESSORIES.

We have recently had our attention called to a series of appliances for the photographer of a somewhat novel character, and which have been rendered necessary or desirable, by what has been termed the "cardomania." The appliances to which we refer, are the productions of the scene-painter, and are the work of Messrs. Bull, Brothers, of Great Queen Street.

There can be no question that the peculiar style of portrait which has become popular in album pictures, has given licence for, if it has not rendered imperative, a much wider range of accessory and scenic affect, than would be permissible in the sober simplicity which should distinguish miniatures generally. This fact admitted, it will follow without question that fitness, keeping, and variety, should always distinguish these accessories. The backgrounds and profiles of Messrs. Bull, are, if selected and used with judgment, pre-eminently well fitted to supply the requirement which this new and popular style of portraiture has created in the photographer's equipment.

Of painted backgrounds, we have seen a very choice selection with a great variety of subjects, representing interiors, close scenes, and open landscapes. These are all well drawn and carefully executed with a view to photographic effect. The greatest novelty, however, consists in a series of ingeniously contrived accessories in profile, arranged so as to combine with each other in almost endless variety. Columns and pedestals of every order, balustrades and vases, book-cases, chimney-pieces, writing-tables, &c. As may be easily conceived, accessories in this form admit of a variety of effect which it would be impossible to obtain by any mode of combining the actual furniture of the studio. One of the first questions which will arise to the mind of the artistic photographer will be as to the possibility of combining painted accessories so as to secure anything like true perspective, and light and shadow. It may be stated that the entire value of such adjuncts will consist in the ingenuity with which these difficulties have been met in contriving the series, and in the skill with which they may be arranged by the photographer. Messrs. Bull have done their part of the work with much judgment and forethought, and if an equal amount of ability be shown in using the profiles there will be no danger of incongruous effects. Each piece is contrived to stand alone, and to fit to all the rest. A pedestal may be used alone, or surmounted by a column, or by a vase; or joined to a balustrade, &c., the drawing, light, and shadow being in all cases made to correspond. For interiors, the chimney-piece may be surmounted with a clock, or chimney-glass, &c; a book-case, writing-table, or other adjunct of the library may be combined. A piece of well managed drapery will often be found very valuable in concealing the profile edge in the junctions and allow more latitude of position.

As we have said, the subjects are painted in a neutral tint suitable for photographic effect the backgrounds are on rollers, and the profiles sufficiently thick for rigidity without being heavy. The pigments are applied in distemper, so skilfully managed as to be perfectly flexible and free from danger of cracking.

As to the question of economy, the profiles, we believe, are, in all cases, less than fourth of the cost of the solid accessories; in some cases much more, and in some instances, such as book-cases, &c., they are easily used where real objects would be altogether beyond reach. The important point will be in all cases to use them with judgment: to avoid combinations incongruous or impossible in their actual relation; to observe that the light on the model and on the accessories is from the same source, and so to place each object, that the view it presents to the camera is compatible with perspective of the drawing in the scene or profile. Our only misgiving regarding the use of such articles lies in the possibility of abuse. For is it not a common thing, without such facilities for error, to see huge columns, and stone balustrades built upon carpets, and rich drapery hung in the open air? We hope, however, that the very multitude of effects rendered possible by such accessories as those under notice will render imperative a consideration of their harmonious use, and that the readers of the Photographic News at least will not contribute to swell the examples of such incongruities in pictorial delineation.

THE IODIDES: THEIR CHEMISTRY APPLIED TO PHOTOGRAPHY.

BY PROF. F. A. BOSSARD.*

Let us now return to the decompositions. To make it yet more comprehensive, I will give the following illustration: —165 grains of KI (+HO)+170 grains of $AgONO_5$ (+HO)=AgI+$KONO_5$+(2HO), we add the 165 grains of KI to the 170 grains of $AgONO_5$; then we have 165+170 =335 grains of solids in a mixture with water, in which is the equivalent of AgI=234 (grains+the equivalent of $KONO_5$=101 grains), thus giving together 234+101=335, which is the weight in full solids in the water. By filtering the whole, washing the AgI with pure HO, and drying it, we have the AgI separate, and by evaporating the total amount of HO we have the $KONO_5$ as solid.

I have been told by photographers: "It matters not whether I add iodide of potassium or iodide of silver to the bath, since iodide of silver is introduced in either case;" but they were not aware that, by introducing iodide of potassium, they obtain by double decomposition nitrate of potash as well as iodide of silver, and it is certainly of some consequence whether we introduce much nitrate of potash into the bath or not. Supposing we should, in the same manner, say—let us add iodide of iron to the bath, for it forms AgI just as well as the KI does. Truly it forms AgI, but still it forms $FeONO_5$ (protonitrate of iron), just as well as iodide of silver; therefore, by adding FeI to the bath solution, it amounts to the same thing as if we added iodide of silver and protonitrate of iron, or even a developer to the bath.

The best and most proper way to make and iodize a new bath is as follows:—Allow 9 grains of AgI to the ounce of crystallized $AgONO_5$; supposing I wish to make a bath of 4 ounces (avoirdupois=437·5 grains per ounce). As above stated, I use 9 grains of AgI to the ounce of crystallized $AgONO_5$. Therefore, 9×4=36 grains of AgI is wanted. This AgI we propose to make by a double decomposition between the KI and the $AgONO_5$. Now, to make exactly 36 grains of AgI, how much KI and how much $AgONO_5$ do I want? By following these rules, any one can always obtain a properly constructed and iodized bath. I figure it out in the following manner. We have two unknown quantities to work with, therefore let us distinguish them thus:—

Let x be equal to the quantity of $AgONO_5$,
and y be equal to the quantity of KI.

Wherefore x is equal to the product of $AgONO_5$ by 36 divided by AgI; and y is equal to the product of KI by 36 divided by AgI.

Thus ($AgONO_5$) 170×36=6120, and it, being divided by the equivalent of AgI)=234 would yield $\frac{5940}{234}=25\frac{90}{234}$ grs. Therefore $x = 26\frac{36}{234}$; and $y = 25\frac{90}{234}$.

Consequently, I would dissolve x grains of $AgONO_5$ in about two ounces of water; mix the two, and wash the precipitated AgI well. Lastly, I would keep 6 ounces of water upon the precipitate, and add the crystallized $AgONO_5$, stir up, and the whole will dissolve entirely; then dilute until it contains 45 grains per oz.

Whatever iodide we use in the collodion, by mixing it with the bath we obtain a nitrate of its base. Example: NaI+$AgONO_5$=AgI+$NaONO_5$, or CdI+$AgONO_5$=AgI +$CdONO_5$. The bromides are analogous to the iodides. Some of these nitrates have more tendency and power to decompose and develop the iodide of silver film, which has been acted upon by light, than others; and, since an extraordinary amount of sensitiveness can be formed by allowing the formation of certain nitrates, I deem it worthy to study the relative developing power between the different nitrates.

The most sensitive film is obtained by allowing the presence of a nitrate of such a base as has a tendency to *decompose* and *develop* the film of silver salts which has been acted upon by the light. Protonitrate of iron does it, and it should be upon the plate while exposed in the camera.

The manner in which the protonitrate of iron is formed upon the plate is not of so much importance as the quantity present; however, when it is formed upon the film by double decomposition, we have to take into consideration both salts which are formed and what effect each has upon the film. We come to about the same result by adding a very small quantity of protonitrate of iron to the bath, instead of the proto-iodide of iron to the collodion, especially since the FeI is so exceedingly unstable.

Some operators say that iodide of iron renders the collodion very sensitive. This is a mistake; it is no longer the proto-iodide of iron which renders the film sensitive, but the protonitrate of iron in combination with the silver. Should the proto-iodide of iron render the collodion itself sensitive, we should no longer require a bath of silver to sensitize.

Iodide of silver, whether it is made of iodide of cadmium, silicum, potassium, sodium, ammonium, or iron, is, under all circumstances, equally sensitive, provided there are no other nitrates or foreign substances with it; but if their respective nitrates are present, as is the case upon the collodion film, then the iodide of iron is at the very head and front of the whole list of iodides known.

To sum up the question, I would state, that it depends entirely upon the nature of the nitrate which has been formed by double decomposition. Another point we have to bear in mind is, that 5 grains of some iodides contain more iodine than 5 grains of others, according to the atomic weight. Therefore, the iodides are not all alike in strength, for 438 grains of iodide of ammonium contain no more iodine than 149 grains of iodide of sodium.

Let us coat a piece of paper with iodide of iron, then coat it with nitrate of silver (in the dark-room), then let us expose it while wet in the camera, and we obtain a picture which we need not develop. So it is with collodion that contains the iodide or bromide of iron, or both; it forms its own developer, and, if long enough exposed, does not require to be developed, for the picture appears gradually of its own accord, since the developer is formed by double decomposition. The chief trouble is, that the iodide of

* Continued from page 534.

iron is so readily decomposed in the collodion, that it is constantly unstable, and is converted into oxide of iron and free iodine, which colours the collodion red, and this free iodine, with nitrate of silver, yields iodide of silver and free nitric acid, since it has no base to act upon or to combine with. When we expose a plate with such collodion, which has turned red, owing to the decomposition of the iodide of iron, we form free nitric acid by dipping it in the bath, on account of the free iodine, and the free nitric acid first prolongs the exposure; secondly, it causes stronger blacks and finer whites; and thirdly, it prevents intensity; for, since nitric acid dissolves metallic silver, how much more will it prevent the formation thereof, and the intensity in a negative is but metallic silver. Nitrate of potash and nitrate of iron both whiten the film, but the nitrate of ammonium, being of an alkaline nature, does not thus whiten it.

Now I would state, that if we desire sensitiveness, we should see which is the best way to obtain a nitrate upon the sensitive silver film of a nature which has the power to decompose and develop the sensitized and exposed film. Now, the manner in which it may be done is left to the operator. Whether added as a nitrate to the bath, or as an iodide, a bromide, or even a chloride, to the collodion, it should, under all circumstances, form a nitrate of a slightly acid nature, like that of iron, and a nitrate which has power to develop the picture; and thirdly, it should be introduced in a pure state and in a small quantity only. There is hardly an end to this important subject, and I have still another important point to explain; I am only sorry that time compels me to make it as short as possible.

The above facts are sufficient evidence that it *does matter* what iodide is used for obtaining sensitiveness.

Now, let us see whether the kind of iodizer has anything to do with intensity or not. We have seen that the different nitrates possess different decomposing powers. We have alkaline nitrates, neutral nitrates, and acid nitrates. Of all the different kinds the alkaline nitrates possess the greatest decomposing power, as, for instance, the nitrates of ammonia, magnesia, and soda, and their iodides and bromides, all yield an excellent collodion. I especially recommend the iodide of sodium because it freely dissolves in the collodion, and does not decompose as readily as the iodides of magnesium or ammonium. When a collodion becomes coloured, and even turns red finally, it is almost unfit for negative purposes, for free iodine, producing free nitric acid as above-mentioned, prevents intensity. I only intend at present to treat on the iodides, otherwise I should have brought forward other reasons for intensity.

The presence of a certain amount of acid on the plate is necessary, whether we form it by iodine in the collodion, or whether the collodion is colourless and the bath contains the acid, is not of so much consequence as the quantity present. I have noticed that many English and French photographers prefer a colourless collodion with a slightly acid bath. An excellent photographer in Paris told me the following.

"I have used iodide of sodium in my negative collodion for the last four years, and I am satisfied that there is nothing better; but I have to make it myself, as I cannot depend on what I buy being pure. I prefer my present plan—to make the iodide of sodium—to all other methods."

We have seen that the iodides whose bases yield with nitric acid the strongest alkaline nitrate, and whose iodides are not easily decomposed, will yield the best negative collodion. However, most iodides yield, with a nearly neutral bath, a good negative, yet some stronger than others. If the bath is neutral, the collodion should be coloured; if the bath is too strongly acid, the collodion should be neutral; it depends principally upon the nature of the base of the nitrate. Another thing to be considered is, when we develop a plate we develop nitrate of silver into metallic silver, which causes the intensity; and consequently, when there is but little silver in a bath, we cannot expect to develop much. When we develop a picture, and it is not quite intense enough, we may improve it by developing with a weak silver solution, and when the developer is exhausted we may add to it. By such means we can nearly always remedy the want of silver in the bath, or rectify a weak negative.

In conclusion, I would state, that if we desire a strong negative we should first have a sufficient quantity of nitrate of silver; secondly, not have too much acid in the bath; and thirdly, use an iodide in the collodion which yields by double decomposition a nitrate of rather an alkaline nature.

I think I have now shown that the kind of iodizer employed has something to do with both intensity and with sensitiveness. I could give more evidence if desired, but time will not permit me just now. I hope everyone will agree with me on this subject; if not, I would like to have some one prove the contrary, as it is a subject worthy of discusssion.

PROTOSULPHATE OF IRON DEVELOPER.

BY COLEMAN SELLERS.*

When, in the very beginning of my studies in the photographic art, a professional operator told me,—"You are only wasting time; unless you wish to follow photography as a business, you had better let it alone." I did not feel discouraged, but rather stimulated to find some way so to systematise the various processes, as to avoid the trouble he pointed out to me, viz., chemical solutions getting out of order during the intervals of an amateur practice.

There was much truth in what he said about the necessity of having all things fresh, but when the matter came to be fully looked into, collodion and developer seemed to be the only real troubles. It is very annoying to find after an absence of some days from one's laboratory, that a picture cannot be taken in a hurry because there is no developer mixed, and the collodion has dried up. As to this latter trouble I will at present say nothing, but, as I have headed the article Protosulphate of Iron, will confine my remarks to that best of all developers.

A solution of protosulphate of iron, say four ounces to thirty-two of water, when freshly mixed, is more or less turbid, owing to a small quantity of basic persulphate of iron on the surface of the crystals; after an hour's rest this persulphate will have deposited itself, leaving the liquid clear. If in this condition it is filtered, the whole quantity of solution can be obtained quite clear, but will not remain any length of time without absorbing more oxygen and depositing more of the persulphate; should acetic acid be added to it, no precipitate will be formed, as the persulphite still forming will be dissolved by the acid and thus impart a dark colour to the solution.

If, when the iron solution is quite clear, it be filtered into the proper quantity of acetic acid, say thirty-two ounces into six ounces of acetic acid, the solution will be very clear, and if placed in an open bottle in a place where it is not liable to be disturbed, it will be found that for many hours no change will take place, but that after a day or two the liquid will have turned brown to the depth of about one-quarter of an inch, and this colour will extend downwards very slowly day by day—as fresh oxygen is absorbed, and the persulphate is dissolved by the acid nearest to it. This experiment has suggested to me the following way of preparing iron solution, ready for use, so as to be sure of its keeping.

Proceed exactly as I have above described, *i.e.*, filter the iron solution so that it shall be quite clear, and when it is found to run clear, let it drop from the filter into a bottle containing the quantity of acetic acid usually put to the developer, about one to five.

As soon as it is all filtered, and before it has time to absorb any oxygen, pour it into a number of small bottles varying in size from one ounce to six ounces, taking care to

* From the *American Journal of Photography.*

fill each to overflowing, then cork them up in such a way as to exclude all air; finally, tie down the corks with strings. In this condition the developer has, in my hands, kept very many weeks, and is at all times ready for use; if a small quantity is wanted, a small bottle is opened and used, and thus none is wasted. In my rambles in the country I have always thus taken my developer ready mixed, and have always had it clear and in good working order.

One caution I must give in regard to the mixture as above. No alcohol must be put into it to assist its flowing, as the alcohol is apt to be excited by the acetic acid into acetic fermentation. But the alcohol can be added when about to be used.

The reason why the iron solution should be filtered into the acetic acid, and not have the acetic acid added to it after filtration is, that the acid tends rather to prevent the persulphate forming, and gives time to filter and bottle; I consider this way of keeping the iron solution of the greatest importance.

My dark-room may be unopened for weeks, the bath left in good order and protected from too much evaporation; collodion kept in a cool cellar in the dark; iron solution ready for use as above described, and hypo solution for clearing in a well-corked bottle, are the essentials for work. Glass can be got ready in a moment (thanks to Mr. Kuhns) with a cloth dipped in a mixture of alcohol and acetic acid, then dried with paper, and when the picture has been taken it can be flowed with a solution of gum-arabic to which aqua ammonia has been added to make it keep. Since the adoption of the above arrangement photography has ceased to be a labour, and all things are ready at all times to catch a pleasant reflection.

THE COMPOUND ALBUMEN PROCESS.

BY MR. NOTON.*

It is essential to success in coating plates with albumen that the atmosphere of the place in which it is to be done is entirely free from dust or fibres, and naturally damp, with a temperature of 60° Fahr. Such not being the case in this room, I must ask you not to expect that I shall cover the plates free from defects in the presence of those photographic enemies.

The quality of the glass plates must not be overlooked. Plate glass is of course the best, especially where contact with another plate is required; but negatives upon flatted crown will do, either for printing upon paper or reduction in the camera.

A strong solution of soda with whiting will clean them, if new, or not too bad; this may be done the day before they are wanted. Rinse them well under a tap, wipe dry with a photographically clean cloth, brushing the fibres off when the elecricity has settled, and put them into a rack, with the face side to the left hand.

The albumen is the next consideration. The fresher the eggs, and if from country hens, the better. Crate eggs, not kept long, will answer pretty well. Darkness, and a low temperature, down to 40° Fahr., is good for albumen, either in or out of the shell.

The conversion of the organised mass of albumen to a liquid by beating, or disintegrating as I call it, cannot be too well done, for whatever process it is required, whether plain or salted; and should be prepared about twelve hours before it is to be used, and then filtered.

Pour the albumen upon the dry glass plate as you would collodion, and if it does not flow to your satisfaction, make it do so with a quill, a camel-hair pencil, or your finger: you will also have any quantity of another enemy, namely, minute bubbles. Three or four years back, I thought if I could but get albumen to flow as easily as collodion, I should be set up. I tried steaming, but found it did not answer, as part of the surface of the plate got dry before the albumen reached it. Ultimately, I hit upon the idea of mopping the plate over with a strong solution of soda, washing off front and back, and whirling rapidly for about ten seconds; I then found the albumen flowed as well as collodion. Another great advantage results from this—the plate is made chemically clean at the moment you are going to cover it: there is no risk of contamination from a cloth, nor fibres set afloat in your operating room. Still you must not pour the albumen on as you would collodion: albumen must never drop. The flange of the neck of the bottle must be in contact with the centre of one side of the plate. Tilt the bottle so that a quantity comes out on about the centre of the plate, then incline the latter up and down to spread the albumen. Keep working the liquid round and round, then cross-ways and length-ways of the plate several times, to mix with the moisture on it. Pour off into a cup, then whirl, slowly at first, increasing the speed afterwards; detach from the holder and slip the now albumenized plate on to a hot water plate to dry, which will take about a minute. When cool, sensitize and wash thoroughly; if a second coat of albumen is intended to be put upon the first, this sensitizing may be done in daylight; from the washing baths transfer it to a bath of iodide of potassium, or chloride of ammonium, then wash well again, fix the plate upon a holder, give it another swill with water from a jug, whirl rapidly, and coat and dry as before.

The plate when cool is ready to be re-sensitized in the dark room, or put away in a plate box without, for keeping.

If in time, dust or fibres get on the surface of the uncoagulated albumen, it may be washed off, and the first film re-coated.

* Condensed from a paper read at a Meeting of the Manchester Photographic Society, November 6th, and reported in the Society's organ.

Proceedings of Societies.

North London Photographic Association.

The usual monthly meeting of the Association was held in Myddelton Hall, on the evening of Wednesday, the 20th of November, G. Shadbolt, Esq. in the chair.

The minutes of the previous meeting having been read and confirmed,

Mr. T. Ross exhibited and explained a set of apparatus for producing 9 × 5 panoramic pictures.

In answer to various questions, he stated that the complete set of apparatus, comprising lens, camera, stand, bath, printing-frame, rest for cleaning glasses, box, &c. cost £22. The glasses with the required curve were 18s. a dozen. After a desultory conversation on the subject, some comments were made on the curved appearance which the lens gave to a straight road.

Mr. G. Wharton Simpson said that if the camera were placed so that a straight horizontal line were parallel to the axis of the lens, it would be delineated as a straight line.

The Chairman denied this, and said that all horizontal straight lines would be produced in curves by this lens when the picture was flattened out.

Mr. Foxlee inquired of Mr. Ross, if the lens would need to be focussed. Mr. Sutton said it would not.

Mr. Ross said unquestionably it would require focussing, as the aperture was large in proportion to the length of focus.*

After some further conversation on the use of the shutter with which the camera was furnished,

Mr. Dawson said he never could see the advantage of such shutters, nor the propriety of calling them instantaneous. The most simple and rapid means of uncovering and covering the lens that he knew was, simply using a piece of black cloth in the hand. Any shutter attached to the camera had a tendency to shake it when in use.

Mr. Ross thought there was no necessity for shaking the

* To obtain the value of the pencil incident on the first refracting surface of the panoramic lens, square the diameter of the aperture in the middle of the lens; multiply this number by two, the square root of the result gives the equivalent diameter of the pencil. The diameter of the stop in the one exhibited is 25 inches, and by the above process it will be found that the equivalent diameter of the pencil is ·3535. The focal length of the lens is 5·5 inches, divide this number by ·3535 we then get the ratio of the diameter of the stop to the focal length, which is nearly 1-16th, so that the aperture may be considered large for a view lens.

camera if carefully used. This shutter had the advantage of exposing the foreground first.

Mr. Dawson denied this, and regarded the idea as entirely a fallacy. The fact that the shutter exposed one part of the lens first, simply had the effect of a diaphragm. The whole of the image would be produced by the small portion uncovered.

Mr. Ross said that would only be the case with a single lens.

Mr. Dawson said that views were usually taken with single lenses.

Mr. Simpson thought there was some misapprehension on the subject. With regard to combinations of lenses, a shutter exposing the bottom of the lens first would unquestionably expose the foreground first. But the same would hold good, to a certain extent, of single lenses. If the shutter were in immediate contact with the lens, then the exposure of one part before the rest would have a similar effect to a diaphragm. But if the shutter were placed at a distance in front of the lens, it could be placed so as to expose any part of the view first, by shading or cutting off the rays from the other portion. The shutter in question might be raised in such a manner as to shade off the sky during part of the exposure, and give the foreground more exposure. The shutter so placed, really obstructed the view of the lens, if he might so speak, and prevented it seeing the sky.

Mr. Seely remarked that if a central stop in front of the lens were placed at too great a distance from it, part of the view was cut off, and the field limited.

The Chairman said anything placed in front of a lens so as to cover it partially, must act either as a diaphragm or an object. The question of distance, as Mr. Simpson had remarked, determined which. If it were at a certain distance from the lens, it would act as an object cutting off part of the view as the corner of a house might sometimes do.

After a few further remarks the subject dropped.

Mr. Martin then read a paper which had been entrusted to him by Mr. Hislop, who was unable to attend. The paper was on the advantages of using simply collodion plates, and affirmed that whatever characteristics a collodion possessed when used in the wet process, would be retained when excited, carefully washed and dried, without the use of any preparation or preservative. The article will appear at length in our next.

The Chairman asked if the plates were always coated with some preparation, or were used with a coating of collodion on the bare glass?

Mr. Martin said that the film had a tendency to leave the glass, and that Mr. Hislop therefore always coated the plate with a very dilute solution of albumen prior to applying the collodion.

Mr. Simpson suggested that in that case, Mr. Hislop was overlooking the fact that the organic matter thus supplied would have a chemical action, as well as the mechanical one of attaching the film.

Mr. Martin said that Mr. Hislop coagulated the albumen by holding the plates before a brisk fire, after coating them.

Mr. Simpson said that heat so applied would dry the albumen; but would not coagulate it. Dried albumen was not coagulated by heat.

Mr. Martin said the plates were held before the fire previous to drying, whilst the albumen was still wet.

Mr. Simpson very much doubted whether it was possible with albumen so highly diluted—8 parts of water to one of albumen—to coagulate it in that manner at all. Heat so applied, would, he apprehended, dry without coagulating it.

After some further conversation, in which Messrs. Shave, Moens, Dawson, Bingham, and others, took part,

The Chairman remarked that Dr. Hill Norris had announced the fact as early as 1854, that a washed collodion plate was sensitive to light. Subsequently, Mr. Barnes made use of the identical process which Mr. Hislop was now recommending, namely, that of coating the plate first with dilute albumen, and then applying collodion, exciting, washing, and drying. Regarding the action of the albumen, suppose it even were coagulated, the nitrate of silver bath would come into direct contact with it, and form an organic compound. Or if even nitrate of silver had not come into contact with it in sensitizing, it would in developing; there was no question that the albumen would form an organic compound with the free silver, which must come into contact with, and materials be supplied to aid in forming the image, and giving intensity. Even were there no albumen coating, it should not be forgotten that the pyrogallic acid supplied the organic matter, and thus aided in getting the image. He was not aware whether a simply washed collodion plate would give an image with an iron developer.

Mr. Simpson said it would—he had tried it; but the image was very thin and weak.

The Chairman said even then acetic acid would probably be used, and still supply the organic element.

Mr. Simpson said acetic acid was used in the developer.

Mr. Dawson remarked that the nitrate of silver would doubtless come into contact with the albumen, as it would penetrate through the collodion. He remembered once exposing a plate on the wrong side. The result was an image which could be seen by reflected light on the glass side, but not on the collodion surface. The image was really between the glass and collodion film.

Mr. Simpson had on one occasion a negative which split from the plate, and left a very definite image on the surface of the glass. Regarding the operation of the albumen, it was proposed some years ago to be used in the wet process as a certain means of gaining intensity. He remembered Mr. Hughes showing him some remarkably fine negatives obtained in that way. They had the rich brown tint of albumen, the great drawback was, that they soon spoiled the bath.

Mr. Bingham asked if the albumen was coagulated in that case.

Mr. Simpson said it was not.

The Chairman referred to Mr. McNab's use of a similar process, and his difficulty in its spoiling the bath, and the plates not keeping. He (the Chairman) then suggested to him the application of protosulphate of iron to the albumen film, which at once made them keep, and, indeed, restored some which had shown spots of mouldiness.

Mr. Martin remarked, in regard to the effect of dry heat, up to a temperature of 130° it dried, and did not coagulate the albumen. What would be the effect of a higher temperature he had not tried.

Mr. Simpson suggested, that from his experiments in that direction, he was inclined to think that a suitable non-contractile collodion would adhere without any previous preparation of the plate.

The Chairman had not found any collodion that would do it.

Mr. Martin thought in the choice of a suitable collodion lay the whole question. Many collodions could not be worked free from stains when merely washing.

After some further desultory conversation, the proceedings were terminated by the usual votes of thanks.

The American Photographical Society.

The Society held its regular meeting for October, on Monday evening, 3rd inst., in the Chapel of the University; Vice-President Joy in the chair; G. H. Babcock, secretary *pro. tem.*

Water in Collodion.—Mr. Tillman stated that he had received a letter from Dr. J. M. Sanders, in which the doctor claimed that the addition of about two drachms of water to the pint of collodion was a great improvement, especially for ambrotypes; the impression was more brilliant and whiter.

Mr. Kuhns.—Water in collodion is not new. Indeed, most photographers complain that in the ordinary methods of making collodion they introduce too much water. Whether or not there is advantage in a small quantity of water in collodion, there is no doubt there is a limit, for certainly too much water will produce the most troublesome markings and other defects.

Daguerreotype Experiments.—Mr. Johnson presented some results of experiments to illustrate the persistence of the sensitiveness of Daguerreotype plates. The plates were coated with iodine only, and exposed in a camera before brightly lighted objects for several days; in one case for fourteen days. New objects were also from day to day added to the field. The objects were all depicted on the plates, even those placed in view on the fourteenth day.

Specks on Photographs.—Mr. Babcock stated that the photographs made a year ago for the graduating class in New Brunswick, had by degrees become almost ruined by the appearance of minute white specks all over the surface. He would like to have the opinion of some of the members as to the cause.

Mr. Kuhns being called upon, said it would be impossible to do justice to the case without a careful examination of the specimens. The defects in question may come from a variety of causes, drops of acid, salt, particles of dust, foreign matter in sizing, paste, &c. I suspect they were not preserved in a proper place.

Mr. Babcock.—A dozen of those which are spoiled, were kept in a large paper envelope in a dry room of a private house.

Mr. Kuhns.—I would look then for an explanation to the paper used, or to the unskilfulness of the photographer.

Photographic Notes and Queries.

Toning Bath.

Sir,—I beg to forward for the readers of your valuable News a receipt for toning.

Chloride of gold	2 grains.
Common salt	2 drachms.
Distilled water	8 ounces.

Place the print from the printing frame in the above bath, and tone to a deep purple or blue. Then fix in hypo, and the prints will assume a beautiful carmine purple, I remain, yours &c.,

A. H.

Splitting of the Film.

Sir,—After reading with some interest the suggestions of various correspondents addressed to a "Perplexed Amateur," in the current number of the Photographic News, I am inclined to the opinion that the adoption of the proposed precautions, would not entirely prevent a recurrence of the splitting up of the film. Although a large number of pictures taken upon Fothergill plates, may oftentimes be developed and dried without the occurrence of the annoyance under consideration, yet the experience of your 'correspondents' proves its occasional appearance. I have noticed myself that the perplexity is more likely to occur when working upon stereo or small sized plates, than upon larger ones; this may possibly arise from the fact that the dried collodio-albumen film possesses less elasticity towards the marginal portions of the plate, than in the central parts. I agree with Mr. Keene that the ten volumes of water added to one of albumen dilutes the latter to too great an extent for giving the most efficient and adhesive mixture. The question, however, under consideration is not so much with respect to the general adherence of the film to the glass, or a liability of its detachment from the edges, but rather of unequal contraction. In fact the attachment of the edges of the film to the margins of the glass by the aid of varnish increases rather than diminishes the difficulty to be overcome. I do not think, moreover, that the introduction of the salts of bromine, or, indeed, the nature of the sensitizing compounds generally, have any immediate connection with the defect complained of. The avoidance of the difficulty must rather depend upon the alteration of the physical character of the collodio-albumen film, so as to render it less horny and contractile. This may be effectually accomplished by the application of a preservative solution containing an admixture of grape sugar combined with the albumen. This mixture may be easily and uniformly prepared, as I have previously noticed, as follows:—

Raisin extract	1 vol.
Albumen	1 ,,
Water	1 ,,
Ammonia	⅔ fluid oz.

Agitate the whole together, and filter after the lapse of a week or more, through ordinary filtering paper; it will improve by keeping. Your correspondent will find that by substituting the above for the ordinary albumen mixture, he will obtain a film possessing sufficient elasticity and adhesiveness as entirely to prevent the repetition of the annoyance to which Fothergill plates are occasionally subject. I trust that a "Perplexed Amateur," will by no means discard the collodion which he has been lately using, but test the efficacy of the various suggestions in connection with the sample so eminently suitable for the trials. He will, of course, favour us with the results of his future experiments for our mutual edification and instruction.—Yours truly, T. Sebastian Davis.

Sir,—Many remote and ingenious causes have been assigned by your other correspondents in last week's News, for the difficulty experienced by a "Perplexed Amateur."

The proximate and true cause I believe I pointed out from my own very recent experience.

Though it may be too simple and unimaginative to be attractive, I would urgently recommend a "Perplexed Amateur" to give it a trial, and let me know the result.—I am, sir, yours respectfully, Edwyn Offer,

Manchester, Nov. 26th.

Sir,—If the correction is worthy the trouble, I would write that in my reply to "Perplexed Amateur," last week, the compositor made me say *gum*, instead of *grind*, the plates. A small word makes a vast difference in sense. Would you inform me in your correspondence corner, can I procure No. 2, Vol. I., which I have somehow lost.—Very obediently yours, M. Willett.

Dear Sir,—I tender you my best thanks for the valuable space you have kindly devoted to assist me out of my perplexities, also to those gentlemen who have so promptly offered their advice.

I, like Mr. Edwyn Offer, was ready enough to lay the blame to the hypo, but if he will refer to my letter, he will find that as a test, I proceeded no further than developing the picture, when on drying, the film split up as stated; consequently the cause could not be from either the alkinity, newness or strength of "poor hypo."

Mr. M. Willett suggests varnishing the edge of the plates, and drying in an oven; both these precautions were taken, the former is a good remedy against the film being washed off the plate, but the splitting up is quite another disease. Mr. Keene is so high an authority on dry plates, that I regret I cannot accept his suggestion that the *weakness* of the albumen wash is the cause, if this were so, a simply washed plate would be still more liable to split up; besides, with the wet plates, no albumen was used. I have tried his remedy of flooding the plate with albumen after fixing, and saved several plates, but I was anxious, if possible to find out where the fault lies, and if possible, get rid of the complaint altogether.

Teesdale appears to have suffered in like manner to myself, and his suggestions are practically the same as your own, viz.: it is either the collodion or dirty plates, it may very possibly be the latter, if so, I should like to know how to tell when a glass plate is *really clean;* mine were washed in soda and rain water, well rinsed, cleaned with a mixture of nitric acid, alcohol, and tripoli, and polished off with a clean piece of silk.

Apologizing for troubling you with so long a letter, I remain, yours very truly and obliged, A Perplexed Amateur.

London, November 26th, 1861.

Mounting Photographs.

Dear Sir,—Having read your highly interesting paper with much pleasure, upon the mounting of photographs, I beg to call your attention to a substance that will be found exceedingly useful for the purpose, viz., "Gum Tragacanth," well known in commerce as "Gum Dragon." Its qualifications are as follows: simplicity in mixing; ease in application; not being injurious to the photograph; and readily separating from the mount when required. The mode of preparing is this: in an ordinary marmalade jar put about a dessert spoonful of the gum, three parts filling with cold water. This done overnight, in the morning there will be sufficient paste to mount a number of prints; and if by any chance the surface of the photographs, or the margins of the mounts are touched with the gum, it can readily be removed without injury to either.

Should the foregoing be of any service to your readers, I shall be glad of its publicity.—Yours faithfully,

W. Gregory St. George.

31, *Gloucester Place, Kentish Town, N.W., Nov. 25th,* 1861.

[We have occasionally used a paste made of gum tragacanth, and merely omitted it from our paper on account of the great length to which our remarks had run. We can speak of it as very suitable for the purpose.—Ed.]

Curious Transformation.

Dear Sir,—Some few days since I mixed some gum guaiacum with Ponting's negative collodion, which is perfectly colourless. In about two hours it was of a fine prussian blue; in two or three more of a rich purple, and in the evening of a fine ruby red; the next morning it was bright yellow, and it is now quite colourless again. Not being able to account for this phenomenon; I should be glad to know if any others who have tried this process, have met with anything similar.—I am yours respectfully, H. Cooper, jun.

5, *Aberdeen Park, November 27th,* 1861.

Miscellaneous.

The Province of Photography in Art.—The question of the range of subjects proper for fine art becomes year after year more needful as photography advances. To us it seems pretty clear that, for everything in the way of mere transcript, photography is the thing; it is easier, more certain, more ample, and in almost every respect, as far as this object is concerned, more beautiful, and to crown all, incomparably cheaper. It has already made huge inroads upon this field of art, and is morally sure to monopolize it at no distant day. What photography cannot do is to colour, and to invent. To say that it will never be able to colour would be extremely rash; some glimmerings of that power in photography have already been bruited, and there is no knowing where this, or any other human conquest of the forces of nature will stop. All we can affirm is that, for the present, the sublime and delicious province of colour lies exclusively at the command of man. Of invention, photography has already in its nature and practice a certain very limited property. The power of invention is the conceiving how a thing which does not materially exist, would be, and would look if it did exist; and the photographer who arranges and takes fancy groups, produces, in a sort of way, a result similar to the artist who, with or without models, represents a subject conceived in his mind. But this is, as an almost constant rule, bad invention, and futile photography; it cannot possibly compete with, though it in some degree shadow forth, the power of artistic invention. The imminent condition of fine art appears, therefore, to be the limitation to invention and colour, transcription and record of mere fact of every order being handed over bodily to photography. This does not, however, include human portraiture, which, in its higher walks, has a large measure of invention. There is nothing to irritate or alarm us in the prospect. We shall have the best possible inventions worthy of contemplation. An enormous quantity of art pursued at a ruinous sacrifice of time and labour will find a painless extinction, and the public be thereby delivered from shoals of inefficient trumpery or useless essays; the true and great art will survive; the artist knows and works out his own invention.—*Frazer's Magazine.*

Talk in the Studio.

South London Photographic Society.—The Experimental Committee, in connection with this society, are about to institute an inquiry into the nature of the latent image, and the modes of developing it.

Birmingham Photographic Exhibition.—In our announcement of the prizes in connection with this Exhibition, we referred to it as closed. This was an error into which we had been led by the statements of some correspondents. It is not yet closed, but will be on Saturday. Contributors will then be able to receive back their pictures.

Photographs of Races.—A correspondent informs us that Lord Canning has ordered a collection of photographs to be made of the various races in India. Such a collection, carefully executed will possess great ethnological value.

The Florence Exhibition.—The Italian correspondent of the *Daily Telegraph* says:—The medals for photography are now given, and the "full length" of the King, of which I have before spoken, is at the top of the list. Duroni, of Milan, has the best portraits; Mr. Warren Vernon the best landscapes. A man from Perugia has also some good likenesses. The King has bought the fine pictures of the Colosseum and the Capitol, sent from Rome. Much more justice might have been done to this branch of science had the light been more considered. The photographs are displayed in a semicircular gallery, without the least regard to their shape, size, or their lights and shades. It is a fine collection.

To Correspondents.

*** The Photographic News Almanac will be ready in a few days. It will form a complete epitome of the art, with all improvements, as at present practised.

O. B.—The almanac will be forwarded in a few days. We believe there is no difficulty in working the pistolgraph. We have never seen any solar camera pictures enlarged from pistolgrams. We fear the results would not be very perfect, unless the lens of the pistolgraph was stopped down very much, which would decrease its rapidity. The other lenses you name would be most suitable, and answer your purpose best.

W. H. Warner.—The prints are received, and shall be handed over to the Society at the next meeting. The "Two Bridges" is very charming.

One who works alone.—Acetate of soda has a slightly alkaline reaction, and may possibly, if there be only a slight trace of acid in your chloride of gold, neutralize it. If not, add the slightest amount of carbonate of soda, which will produce neutrality. 2. Hyposulphite of soda may be kept in solution without danger; the term a "fresh solution" simply means one which has not been used before. It is a good plan to keep a piece of chalk in the hypo if it be used more than once. Fresh hypo will not need it. 3. The No. 1 and 2B lenses you inquire about, both answer well for card portraits, and are both exceedingly rapid. The No. 2B covers most perfectly for standing figures, and may be used with full aperture. To get perfect definition about the feet of standing figures with the No. 1B, a diaphragm —not a small one—should be used, which would give the advantage of rapidity to the 2B for standing figures. When both are used with full aperture, we believe they are about equal in rapidity. We have seen excellent results from both. The No. 1B requires, we believe, about 12-ft., and the No. 2B 18-ft. or 20-ft. We have not tried the card lenses of the other maker you name.

F. W. Sutton.—To become a member of the Photographic Exchange Club, it is necessary to send name, address, and pictures for exchange, to the secretary, Mr. Frank Howard, 12, Whittingham Villas, Studley Road, Stockwell.

M. D.—Kaolin may be kept in the stock bottle of silver solution for printing. Care should be taken that it does not render the solution alkaline, as some samples will do.

Sigma.—We are afraid that there will be some difficulty in cleaning a tin still from rust. Can any of our correspondents give information? 2. You may remove the iodide from your old paper negatives with hypo. 3. To take the portrait of an old lady in widow's cap and black dress, use a bromo-iodized collodion and iron development. Since you work out of doors, hang up a sheet, or in some other way form a canopy to screen off some of the direct top light. Use a grey back-ground, and expose long enough. The best mode of separating the white from the yoke of an egg cannot be very well described. It is simply a neat piece of manipulation. Break the egg on the edge of a cup, and separating the halves of the shell slightly, allow the white to run through between them, taking care that the aperture is not sufficiently wide to allow the yoke to follow. Ask the cook to show you the operation. 5. One of the simplest methods of drying plates is to fill a jug with hot water, and lean the plates against it. 6. We believe Dr. Hill Norris's plates, when properly used, generally give good results. 7. We know nothing, except what is stated in the article 8. The Amateur Photographic Association is still in existence. 9. We will inquire. Much of the information you now want you will find in the Photographic News Almanac, which will be published in a few days. We should be glad to see your selection of extracts, or a copy of it at some time.

G. Guyon.—To divide the glass rods to which you refer, take a piece of iron wire, and bend one into a ring, which will easily slip upon the rod; make the ring red hot, and rapidly slip to the part you require divided. On removing it, plunge the rod into cold water. A mark all round with a file first would give more certainty of a true fracture if you are not expert in manipulating. 2. The difference between pure spirit and methylated consists in the fact that the latter contains 10 per cent. of pyroxylic spirit, or wood naptha. This addition to the pure spirit exempts it from excise duty. 3. We do not use distilled water in toning generally, but if you find your common water throws down a precipitate with phosphate of soda, by all means use distilled water.

N.—It was announced some time ago that the present volume would terminate at the end of the year, when an index and title page will be published. Regarding the large pictures of M. Alophe, we were informed by an able professional photographer, who had recently been to Paris, that on a careful examination, he discovered very palpable retouching. We shall hope for an opportunity of seeing them.

An Amateur in Trouble.—To prevent the film leaving the glass during intensifying after the plate is dry, it is important in the first that the glasses be scrupulously clean and dry before collodionizing. A narrow margin of black varnish run round the edge with a camel's-hair pencil, before wetting the plate again, is also an aid. A suitable collodion is imperative in such cases; if, with the precautions we have named, you still lose your films, change your sample of collodion, and try another maker.

F. O. B.—The addition of a bromide may increase the sensitiveness of your old coloured collodion. You may find it useful to mix in small proportions with samples which are too new.

W. B.—Some of our correspondents seem to have a strange notion that they have a claim upon us for private advice, and that by enclosing a stamped envelope they make that claim imperative. If we were to admit such claims our time would be more than occupied in correspondence. Where we answer letters privately it is because we see reason to do so; and the act being one of supererogation entirely, we claim the right to decide the propriety of answering privately, or in the News. Where a reply in the the answers to correspondents will, in our opinion, answer every purpose, the fact of a stamped envelope being enclosed cannot be supposed to compel us to write a private letter. Our time is more than fully occupied at present.

Inquisitive.—You will find a recipe for a toning bath with gold and chloride of lime in the Photographic News Almanac, which will be published in a few days. 2. Your silver bath is probably alkaline. Add a few drops of nitric acid.

W. J. C.—The lens you mark No. 4 will answer your purpose. The price is about £5. You omitted to append numbers to the prints, so that we cannot tell to which the various remarks apply. They are not printed sufficiently deep. Print at least twice as long, and send us some further specimens.

P. N.—We prefer No. 2 on your list. The whole plate triple will suit the length of your camera. A single lens would be of longer focus.

Novice.—You will find particulars of the acetate of soda and gold toning bath in several recent numbers of the News. There is an article on the subject in the Photographic News Almanac, to be published in a few days.

John Crabtree.—We have never used either of the lenses you name. It is impossible to state the time any dry plate will require to be exposed, as everything depends on focal length, the aperture, the light, the subject, &c. From three to five minutes may be an approximation with a lens of 11-in. focus, and ⅜-in. stop.

THE PHOTOGRAPHIC NEWS.

VOL. V. No. 170.—*December* 6, 1861.

PHOTOGRAPHY AND THE INTERNATIONAL EXHIBITION.

THE Committee for Aiding in the Management of the Photographic Department of the International Exhibition is now appointed, and consists of the Earl of Caithness, Mr. Kater, and Dr. Diamond. The two first-named gentlemen are members of the Council of the Photographic Society, and Dr. Diamond is its secretary. Mr. Peter Le Neve Foster, who is appointed Superintendent of the Photographic Department, is also a member of the Photographic Society's Council, and Secretary to the Society of Arts. We hope from the high character of these gentlemen, and their great interest in photography, that the very best arrangements will be secured for a satisfactory representation of the art in the forthcoming competition of nations.

PHOTOGRAPHS BY MOONLIGHT.

WE recently called the attention of our readers to an article in *La Lumière*, in which our notice of Mr. Breese's moonlight pictures was regarded as a "puff of the work of some rich English lord." The article, with its array of figures to prove that moonlight pictures were impossible, was amusing rather than otherwise, and reminded us of an answer said to be given by a Frenchman, who having pursued with great volubility an argument similar to that of M. Gaudin, was told that "facts were against him." His answer was: "So much the worse for the facts." We related the thing as *un fait accompli*. M. Gaudin contended it could not be done. We stated the circumstance as a fact: he responded that it did not accord with any theory *he* knew, and was, therefore, impossible. As we were not in possession of Mr. Breese's method of working, we did not enter into any discussion of the theoretical question, but contented ourselves by re-stating what Mr. Breese said was a fact, adding that the pictures bore evidence of the truth of the statement; and suggested to M. Gaudin more caution in asserting what was possible or impossible in a science like photography. These remarks, M. Gaudin referring to the subject again, chose to regard as "virulent," and as we do not at any time care to bandy hard words with our contemporaries, we were content to let the matter pass without further notice.

At this stage of affairs, however, the matter is taken up by our Liverpool contemporary, who steps in as moderator, and suggests that the whole difference arises out of an error of nomenclature. As we cannot in any sense allow the truth of his explanation, which appears to be made without having sufficiently remembered the case as stated, we must once more refer to the facts. We must first make an extract from the remarks of our contemporary. Referring to M. Gaudin's article he credits him with giving—

"Very philosophical reasons for concluding that in the present state of chemical knowledge, it would be impossible to produce a *bonâ fide* 'moonlight' view. While equally convinced of the correctness of this conclusion, we did not, like M. Gaudin, attribute the assertion made to mendacity, but to some misapprehension. . . . It turns out that the pictures to which allusion was made are instantaneous stereographs of the moon—a very different affair to instantaneous moonlight views, for by all the ordinary rules of language the latter designation would apply only to views illuminated by the reflected light from the moon's surface. Of course Mr. Breese is not responsible for the erroneous nomenclature. We might take a negative of the flame of a candle, but we should not, therefore, be able to take a candle-light view. We cannot doubt that Mr. Breese has made some very considerable advance in exaltation of chemical sensitiveness as the production even of instantaneous lunar images evinces; and we sincerely regret that from so droll an error of language he has been subjected to so much suspicion."

We have simply and emphatically to deny that there is any ground for this solution of the case, or that there is any such error in nomenclature. The authority quoted for such an explanation is a letter from Mr. Brown, secretary of the Birmingham Society, in another page of the same journal. On referring to this letter we find that the term "moonlight views" is repeatedly used, but there is also on one occasion the phrase "instantaneous views of the moon," and upon the suggestion conveyed in this phrase our good friend, the editor of the *British Journal*, not having seen the pictures, jumps to the conclusion above indicated.

In the original criticism which has given rise to all this discussion, and which contained, we believe, the first public notice of these pictures, we were very careful in describing exactly of what they consisted, and gave just such information as to their mode of production as we received from Mr. Breese. We here quote from our description given at the time:—

"There were three pictures rendering moonlight effects. One is a moonlit sea, with the play of the moonbeams on the water. Another is the moon itself in the midst of a mass of cumulose clouds, which are tipped with silver, and rendered more or less transparent throughout by the moon's light. The third is an interior with the figure of a lady looking out of the window, through which is seen a moonlit sky. The figure is, of course, little more than a silhouette, the edge of which is traced by a well-marked line of light. The white lace sleeve on the arm which rests upon a table underneath the window is well made out, as is also the polished surface of the table reflecting the moonlight."

A description in nearly the same words appeared shortly afterwards in our contemporary's own pages. How, therefore, he can now suggest that the term moonlight scenes is a "droll error of language," and the cause of the misunderstanding, we are at a loss to conceive. We must, however, distinctly repeat it, these stereographs are views of objects professedly illuminated by the light of the moon, and not simply views of the moon itself. They are decidedly what we have described them to be, or we, and all to whom they have been shown, are the victims of a gross imposture, a thought which since we have met Mr. Breese we have never for one moment entertained. In regard to their instantaneity a word or two may be necessary. We have never described them as instantaneous. That, we believe, is a little modification originating with M. Gaudin. The terms we used in speaking of them were that Mr. Breese stated that they had required "*little more* than instantaneous exposure." In order to do him full justice, we may add that he has since informed us that one portion of the interior, which was from two negatives, had an exposure of about seven minutes, whilst the other portion was really instantaneous. We may add that since our notice first appeared, we have had more than one communication from correspondents who have attempted moonlight pictures, and one who states that he recently obtained a negative of the moon and surrounding clouds, with a simple bromo-iodized collodion and iron development. M. Gaudin tells us that to obtain a photographic image of moonlit clouds, would require an exposure three hundred thousand times as long as would be necessary in sunlight. Regarding such a question, we are simply inclined to quote the old paradox, "There is nothing so false as facts—*except figures!*"

We shall not make any comment upon the "philosophical" character of M. Gaudin's reasons, in which our contemporary joins him, for concluding that "in the present state of chemical knowledge it would be impossible to produce a *bonâ fide* moonlight view," because it has never been stated that these views were produced by the aid of "the present state of chemical knowledge;" but, on the contrary, it has been distinctly claimed by Mr. Breese that it was by the aid of a secret which was *in advance* of "the present state of chemical knowledge"—a circumstance unhesitatingly admitted in another part of the same article.

Since the above remarks were written, Mr. Brown has forwarded a letter to the Photographic Society of London on this subject, which will be found in our report of the last meeting in another page. In this letter it will be seen that a similar description of the pictures is given to that which first appeared in our pages, and a promise is made of bringing the subject, together with specimens, before an early meeting.

It may be necessary to explain the allusion which terminates Mr. Brown's letter, having reference to Mr. Cramb, of Glasgow. Some remarks in a nonsensical article by that gentleman, and some other remarks he made at a meeting of the Glasgow Society, contained unjust and untrue strictures on the Birmingham Exhibition generally, and Mr. Breese's pictures particularly. The fact of being uttered in a respectable society, and printed in a respectable journal, gave sufficient amount of importance to these remarks to induce Mr. Brown to forward to the same journal a dignified refutation of the charges, and a proper comment on what he terms, "a class of men who occasionally act as the self-appointed judges of works they evidently cannot appreciate."

GREEN GLASS FOR THE DARK ROOM.

A short time ago our German correspondent, Herr Liesegang, recommended the substitution of green tint in glass for the orange colour generally used for the dark-room windows, on the ground that it was more pleasant to the eye and quite as efficient in repelling the actinic rays. At a late meeting of the Manchester Society Mr. Petschler, who recently visited Germany, made a similar suggestion, stating that he had seen it used with perfect efficiency in Herr Liesegang's dark-room. He had since tried the experiment himself with success; but he had adopted the precaution of using a screen of yellow underneath the green.

Without denying that there are circumstances in which such a light might be used with impunity—such as the absence of direct sun-light, and a circumscribed area for the admission of light, &c.—we would caution our readers against adopting such a method of illuminating without careful trial in the first instance by exposing an excited collodion plate to the window and then developing it.

At the last meeting of the Manchester Photographic Society, Mr. Sidebotham stated that he had made some experiments with different coloured glass in reference to this subject. He found that the green glass was altogether inefficient, and exhibited a sheet of paper which had been rendered sensitive, and exposed under glasses of different colours. That portion covered by the green glass was considerably darkened. Ruby and orange were the only colours which he found entirely prevented photogenic action. An excited collodion film gave similar results.

We have examined various samples of green glass and yellowish green by the aid of the spectroscope, and have found in every instance that not only are a great portion of, or all the green rays transmitted, but in most cases many of the blue rays as well. The samples of glass which we have found entirely resist the actinic rays, are the silver-flashed glass of an orange yellow, some samples of pot metal of a pure orange, and a few samples of red. Too much attention cannot be given to this subject, as it is of vital importance. Those of our readers who have not ready facilities for testing their yellow glass will do wisely to forward samples to our office for examination. We shall have pleasure in reporting as to their character, but we cannot undertake to say where non-actinic glass can be purchased, as dealers are of course continually changing their stock, and we cannot with certainty say that the quality may not change at the same time.

IRON NEGATIVES AND BRILLIANT PRINTS.

Development.

We now proceed to offer a few further remarks on this subject, which, from press of other matter and duties, has been for some time in abeyance. The developing process, more than any other, requires the exercise of a judgment cultivated by experience. Nothing but experience can be an efficient guide to the eye as to the printing value of the gradations seen in the negative. A few hints, the result of our own experience, may, however, be suggestive.

A singular disparity in the strength of the iron-developing solutions used by different skilful operators prevails. The explanation will be found, probably, in the results aimed at by each, and by the mode of working throughout, which accompanies each character of developer. As a general principle a weak developer will give greater contrast, and a strong developer more harmony and softness. Where the developer is weak its action commences first on the highest lights, and as the development goes on slowly there is a tendency to aggregation of deposit in those parts, so that getting more than their share of the free silver on the plate, these parts acquire density sometimes to the loss of the more shadowed parts, the silver belonging to which is partly thrown down on the lights. With a strong developer, on the contrary, the reduction is rapid and more uniform, the detail in the shadows is rapidly brought out, and the deposit reduced from the free silver is not appropriated in undue proportion by the high lights.

From this view of the case it will readily be seen that the selection of strength and character in the developer must, in some degree, be regulated by the mode of intensifying to be adopted. Where the mode of intensifying by pyrogallic acid and silver, immediately after development with iron, and before fixing, is adopted, a weak iron developer is best; because the pyrogallic acid solution in such a case reduces the silver, added with it, in equal proportion all over the picture, on the half tones and delicate shadows, as well as on the high lights, and unless there has been sufficient contrast produced by the iron, there is a risk of producing a tame, flat negative. Most intensifying processes used after fixing, have, on the other hand, a tendency to exaggerate the contrasts a little, giving the greater intensity in proportion to the high lights than to the detail in the shadows, and thus render, necessarily, an image in which universal detail is prominent, to begin with.

A weak iron developer requires more acid than a strong one. The reason of this will be readily seen on a little reflection. Long continued development with an iron developer has a tendency to produce a foggy deposit upon the shadows, and as a weak developer requires a longer time to do its work, it follows there is danger, unless sufficient free acid be present, of producing fog instead of intensity. Many operators are in the habit of working with a 5-grain solution of iron. In this case it is generally found desirable to add the acetic immediately before use, in order to obtain a full efficiency. We have seen some exceedingly fine pictures in which the proportion of iron was eight grains, and of acetic acid twenty minims. In all cases a slight excess of acid is better than insufficiency, as any deposit on the deepest part of the shadows is fatal to brilliancy.

A solution of protosulphate of iron loses some of its activity by keeping: oxygen is absorbed, and a portion of the protosulphate is changed into a persulphate. This change is at once marked by the solution becoming gradually of a reddish brown. Many operators prefer the developing solution in this condition as having much less tendency to fogging or surface reduction. Where this is the case less free acid needs to be added to the solution. If a stock bottle of a saturated solution of iron be kept, it may be diluted from time to time, as its age, the condition of the weather, and the kind of subject may demand. There are many advantages attending such a plan. We subjoin formulæ for different iron-developing solutions differing in character, but all giving good results :—

1.	Protosulphate of iron	5 grains
	Acetic acid (glacial)	5 minims
	Water	1 ounce.
2.	Protosulphate of iron	8 grains
	Acetic acid (glacial)	20 minims
	Water	1 ounce.
3.	Protosulphate of iron	10 grains
	Acetic acid (glacial)	30 minims
	Liq. Ammon. fort.	3 ,,
	Water	1 ounce.
4.	Protosulphate of iron	12 grains
	Acetic acid (glacial)	10 minims
	Formic acid	12 ,,
	Water	1 ounce.

Each of these developers will give the best results when freshly prepared.

5.	Protosulphate of iron	15 grains
	Acetic acid (glacial)	15 minims
	Water	1 ounce.
6.	Protosulphate of iron	50 grains
	Acetic acid (glacial)	30 minims
	Water	1 ounce.

The last-mentioned will work best when a month or two old, and No. 5 when a week or two old. Alcohol sufficient to make each flow freely must be added; the amount will be regulated by the state of the bath. When the solution is about to be kept before use the acetic acid should be added, but no alcohol until the time of use.

Some of the very finest negatives we have ever seen were developed with a solution made after formula No. 2, which is that used by Mr. Heath. Some equally good negatives we have seen developed by a solution made after formula No. 6, which was that generally used by the late Mr. Lacy. The condition of collodion and bath, and more especially the mode of intensifying, rendered each of these two different solutions just what was wanted for the circumstances.

It should be borne in mind that the use of an iron developer is by no means a guarantee that a soft picture will be the result, or that a short exposure will be necessary. With an old simply iodized collodion, highly coloured from free iodine, a long exposure may be required, and a hard dense picture may be the result of iron development, just as it may be of pyrogallic acid development. A bath in bad condition, from impure silver or other causes, will often give a coarse grey picture which no treatment would make into a good negative. On the other hand rapid and soft pictures may be produced by pyrogallic acid development; but in that case everything must be in the most perfect condition as to age and purity.

The great advantages to be derived from the use of a bromo-iodized collodion and iron development are, first, that under fair average conditions, and such a degree of purity in the chemicals as is easily attained, clean, soft, delicate, and brilliant pictures may be easily secured; and secondly, that these conditions may be uniformly maintained without reference to the ever-varying results of age, &c., which render it almost impossible with a simply iodized collodion and pyrogallic acid development to secure anything like uniformity, either in time of exposure or quality of result.

Notes and Jottings.

No. 10.

On the Combining Equivalents of the Iodides used in Collodion, and the different quantities of Iodide of Silver formed by the use of different Iodizers. Waste Silver dissolved out of the Film by the Fixer.

It is common in giving a formula for iodizing collodion to say add so many grains of an iodide, without reference to its base, thus overlooking the fact that a grain of one iodide by no means combines with the same quantity of silver as a grain of another.

Let us take, for example, the iodides generally used, namely, those of *ammonium*, *potassium*, and *cadmium*, we find that each grain of

iodide of ammonium	contains	·87	grains	iodine
,, potassium	,,	·78	,,	,,
,, cadmium	,,	·70	,,	,,

hence, taking the two extremes, 4½-grains of iodide of ammonium to each ounce of collodion, forms just the same quantity of iodide of silver as 5¼-grains of iodide of cadmium; potassium is just midway between these two, so that if we use half ammonium and half cadmium, the result would be as nearly as possible the same as using potassium only.

Whilst on the subject of collodion, we have made a short calculation of the quantities of silver dissolved off the plate by the fixing agent, and only too commonly thrown away.

Each grain, say, of iodide of potassium combines with a trifle more than a grain of nitrate of silver, or about ·66 grains of metallic silver, so that for every ounce of collodion used, rather over three grains of the precious metal, *or nearly the value of one half-penny*, is thrown down the sink!

Ounces of collodion quickly go, and we should find that at the end of twelve months, these half-pence saved would well repay for the slight additional amount of trouble. By simply using a dipping bath, or appropriating to this purpose a separate tray with a waste pipe to carry the portion of fixer used off into a bottle, to be subsequently filtered and used over again until saturated with silver, the additional labour involved would actually be *nil*.

We have here supposed that *all* the iodide of silver formed is dissolved off, and that the negative image is formed from the silver added to the developer. This, practically, is no doubt the case, little, if any, of the normal iodide of silver remaining with the deposit. Most collodions also form an organic compound with silver which has not been taken into account, so that we may look on it as a margin in our above calculation.

This is not, however, the direction in which the bulk of silver is wasted in the operating room; but, unless by actual experiment, it would be difficult to arrive at anything like an estimate of the value thereof. We purpose, however, through the assistance of a professional photographer, who has kindly placed the means at our disposal, to try such experiments, and to give the result to our readers at a future time. Michael Hannaford.

PHOTOGRAPHIC CHEMICALS;

Their Manufacture, Adulteration, and Analysis.

The salt of phosphoric acid most used by photographers is the ordinary phosphate of soda, containing two equivalents of soda, one equivalent of basic water, and one equivalent of c-phosphoric acid. This salt is prepared by adding to a boiling solution of phosphoric acid, obtained by either of the processes already described, carbonate of soda until no more effervescence takes place upon further addition of the carbonate. If the phosphoric acid has been prepared from bone ash, or if it contains earthy impurities derived from any other source, there will be a precipitate of phosphate of lime and magnesia; these must, therefore, be separated by filtration. The solution will still contain traces of lime and magnesia, and to separate these, a trifling excess of carbonate of soda must be added and the whole evaporated to dryness. Upon now re-dissolving the mass in cold water, the phosphates of lime and magnesia will be left behind undissolved, whilst the phosphate of soda will enter into solution: filter off the insoluble portion and evaporate the liquid over a sand bath until a drop removed on to a cold glass plate deposits crystals; upon then allowing the solution to cool gradually the salt crystallizes out in transparent, oblique, rhombic prisms.

Phosphate of soda so prepared contains 24 equivalents of water of crystallization, but is not permanent in the air, for upon exposure it effloresces and loses 10 equivalents of water, becoming converted into a salt containing 14 atoms of water. In any photographic experiments with this salt it is therefore necessary to remember this fact in calculating the quantities of phosphate used, as the former salt contains 6·66 per cent less phosphoric acid than the effloresced salt. Phosphate of soda (by which salt in ordinary language, is meant the diphosphate with 24 atoms of water) dissolves in 4 parts of cold, and two parts of hot water; it has a slightly saline, but not unpleasant flavour, its aqueous solution has the property of absorbing considerable quantities of carbonic acid, and when kept for some time in glass bottles it corrodes the surface of the glass. When added to nitrate of silver it precipitates a phosphate of silver containing three atoms of silver-oxide to one of phosphoric acid; two parts of the nitric acid originally combined with the silver uniting with the two equivalents of the soda, whilst the third atom of nitric acid with which the third part of the silver was united combines with the one equivalent of water which acts the part of a base, and thus communicates a strongly acid reaction to the liquid. Now, phosphate of silver dissolves readily in nitric acid, and, therefore, the employment of a salt, which gives rise to a separation of this acid upon precipitation is attended with considerable loss of silver. We therefore advise photographers in all cases to examine their phosphate of soda before experimenting with it, and if it turn out, as will most likely be the case, to be the ordinary variety containing only two equivalents of fixed base, to convert it into the triphosphate of soda. This examination can be easily performed; it is only necessary to add to an aqueous solution of neutral nitrate of silver a little solution of the phosphate of soda under trial, when, if the supernatant liquor after deposition of the phosphate of silver, is decidedly acid to test paper, the salt employed is the ordinary phosphate. To convert this into the tribasic phosphate (containing three atoms of base), make a strong solution of it in water, and then add to it at least half as much soda as it already contains. Evaporate the liquid down until a thin pellicle forms over the surface of the solution, and then allow it to cool. When cold, the tribasic salt will be found crystallized out, whilst the mother liquor contains the excess of caustic soda: drain the crystals in a glass funnel in which a glass rod is placed to prevent them falling through, then dry them between bibulous paper, and dissolve them in twice their quantity of hot water. Filter the liquid, if necessary, and set it on one side in a shallow dish to crystallize. It separates out in thin six-sided prisms, which are permanent in the air. They dissolve in five parts of cold water. The aqueous solution has a cooling and alkaline taste, and acts somewhat as if it contained free alkali, as it absorbs carbonic acid from the air, and by the action of this acid, as well as by that of other weak acids, becomes converted into the common, diphosphate of soda. It likewise expels ammonia from its salts. When mixed with nitrate of silver it precipitates triphosphate of silver (the same salt which the previous phosphate precipitates), and leaves the supernatant liquid perfectly neutral.

In addition to the common phosphate of soda there is another phosphate frequently met with—the phosphate of soda and ammonia, a salt in which the ammonia takes the place of one equivalent of the soda; it consists of one atom of soda, one atom of ammonia, one atom of basic water, and one atom of c-phosphoric acid. This salt is a very common one, but is not to be recommended for photographic purposes as it (like the diphosphate of soda) gives rise to a separation of nitric acid when mixed with nitrate of silver. It is, however, of considerable use in the laboratory as a blow-pipe flux, and as a knowledge of the simple blow-pipe reactions is of great advantage to the scientific photographer engaged in research, we think that a short outline of the principal facts connected with this salt will not be out of place. It is prepared by mixing five parts of crystallized diphosphate of soda, and two parts of crystallized diphosphate of ammonia together, after dissolving them in hot water. Upon cooling, the liquid deposits crystals of the salt in question. It may also be formed by dissolving six or seven parts of common phosphate of soda in hot water, and adding one part of sal ammoniac. The solution is then to be filtered, and allowed to cool, when the phosphate of soda and ammonia is deposited in crystals, mixed, however, with a little chloride of sodium. The salt crystallizes in large transparent and colourless prisms which have a saline, fresh and somewhat ammoniacal taste. When exposed to the air they effloresce on the surface, and evolve ammonia. When heated, ammonia and water are given off, and the simple metaphosphate of soda is left under the form of a transparent glass. In this state it acts as a powerful flux, and the salt is consequently much used in blow-pipe operations under the name of microcosmic salt.

The only other salt of phosphoric acid which the photographer is likely to meet with is the phosphate of silver. The precipitate which takes place upon adding either the ordinary phosphate (diphosphate) of soda, the triphosphate, or the phosphate of soda and ammonia to a solution of nitrate of silver is the triphosphate of silver, consisting of three equivalents of silver to one of phosphoric acid. When the phosphate, used as a precipitant, contains only two atoms of alkaline base, nitric acid is liberated, but if there be three atoms of alkali, the supernatant liquid remains neutral. In either case the precipitate carries down with it a little of the nitrate of silver which refuses to dissolve out on washing. The triphosphate of silver is a lemon-yellow powder insoluble in water, and when dry perfectly anhydrous; it becomes of a red-brown colour when heated, and fuses at a higher temperature into a dark brown liquid; on cooling the original yellow colour is resumed. Phosphate of silver is sensitive to the action of light, and has been utilised by Maxwell Lyte in a very beautiful and efficient printing process: this has considerable advantages over the chloride of silver process in respect to permanency, and has been used by us very frequently since the first publication of the process by the inventor. We are, therefore, in a position to speak of its merits, and propose, accordingly, to draw attention to some of its more valuable points in a subsequent article. The other properties of phosphate of silver are as follows:—It is readily soluble in aqueous solutions of phosphoric, nitric or acetic acid, in pure ammonia, or in carbonate of ammonia; less easily in nitrate of ammonia, and scarcely at all in the sulphate of ammonia. Upon evaporating the solution in nitric acid it seems to split up into nitrate of silver and phosphoric acid, the former crystallizing out, whilst the latter remains in the mother liquor.

PHOTOGRAPHY AND ITS STUDENTS.

BY SAMUEL FRY.*

Great Britain is, par excellence, the land of amateur photographers; they now constitute a very large and intelligent body. On the continent of Europe, and in America, although the art is largely cultivated as a profession, the numbers who practice it as a recreation or pastime are very small indeed, comparatively speaking. Now, although it would not be reasonable to expect that more than a per centage of amateurs should attain to excellence, yet the results obtained by them.

* Continued from page 543.

as a body, are of the very highest value, many of the brightest intellects of our day being devoted to the "black art."

Our professional photographers are, as a body, a higher class of men than seemed at one time likely to join the ranks, and the large patronage extended by a wealthy, if not very discriminating public, enables the majority of competent operators to do well, but there is a something wanting; our commercial photographers are evidently impressed with the belief that portraits are the only legitimate field for the art, and even then are almost confined to pictures of small size. On the other side of the Channel, however, there are large firms who carry on operations on an immense scale, whose cameras are yards each way, whose lenses are of dimensions altogether unknown here, whose baths are cisterns, and whose plates of glass are often 40 or 50 inches each way. We have all seen the magnificent results of such enterprises in the grand architectural studies exposed for sale in shop windows, which exemplify that whilst we are acquiring in our private circles, and discussing in our journals, the means of obtaining various desiderata, the French have long since achieved triumphs in these very directions. We exert all our energies to produce lenses which shall give architectural lines parallel on plates of a few inches each way, and yet years ago pictures were exposed for sale in London shops 25 inches each way, and displaying mathematical accuracy in their lines, besides possessing every attribute that a work of art should possess. Again, when Bisson Freres are engaged in taking their magnificent Alpine scenery their staff is composed of about twenty-five persons, and proportionate pains and expense are lavished in every department to enable them to keep up the high character of their works. Yet again, for how long have we discussed various dry-plate processes, and in what inextricable confusion have we been involved, by the publication of conflicting statements which could never be reconciled, and yet whilst we have been, from the large number of witnesses to be examined, detained in doubt and uncertainty, the question has been long settled elsewhere, as the large majority of the pictures just alluded to are done on collodio albumen dry plate. In fact, there are on the Continent, not only in France, but in Germany, Prussia, and especially in Italy, photographers who produce, in the ordinary course of business, pictures on dry plates such as *we* very rarely see. The object of this paper is to encourage photographers to take large pictures; there is great merit in size. In fact, there is a far larger amount of skill required to produce a fine picture of twenty inches square than is often supposed, whilst the commercial value of such productions is indisputable. We shall be called upon next year to compete with the photographers of the world; *we* have given the challenge. We have photographic societies, meetings, journals devoted to it, and an army of volunteer photographers. I assert, in the most uncompromising manner, that the works coming from abroad will astonish us not a little, both in their size and quality, and if we are not sharp we shall lose the day. It would be utterly ridiculous, worse than useless, to fill up one available space with portraits of the conventional stereotyped class. We want higher flights than this, and must not be misled. The ordinary run of large landscape will stand but little chance, the subjects must be very grand, the composition artistic, and the *toute ensemble* of the highest possible character, to compete with our *confrères* from over the water in 1862.

ON SIMPLE DRIED COLLODION WITHOUT A PRESERVATIVE AGENT.

BY W. HISLOP, F.R.A.S.*

Although the various processes for the preserving of surfaces in a state of sensitiveness to light are so numerous, it can hardly be asserted that we have yet attained perfection. Exquisite pictures have occasionally been obtained by almost every process; and yet we are continually hearing of something fresh, or some revival of something old—some new preservative, or some new method of manipulation, is announced as perfection and as simplicity itself. A pamphlet is written, and it comes forth to the public so full of details and precautions as to makes its utility doubtful to those whose aim it is to get *pictures*, and not the pleasure of preparing plates.

The proper line of direction seems now to be to simplify details, and, with the materials which we possess, to endeavour to shorten the manipulation as far as possible.

It may probably be thought to be going too far to say that we have been experimenting in a wrong direction, in devising all sorts of applications to the plate to preserve it; still I have no doubt in my own mind that it will ultimately be found that the effect of these applications has only been to mar and spoil an exquisitely delicate surface, which requires rather to be kept from contact with any extraneous substances whatever.

It has long ago been stated that the dried collodion film is sensitive to light; but the statement has been made in so doubtful a manner, and with such qualifications, that few have ventured even to try the experiment. Among other things, it has been said that the pores of the collodion must be kept open, in order to allow the developing agent to penetrate the film and bring out the picture. Then various substances have been applied to its surface, and in most cases carefully washed off again. and we are told that some mysterious effect has been produced on the film, which enables the desired result to be obtained. Recently we have had several processes in which the great difficulty is the non-adhesion of the film to the plate, rendering some previous operation necessary for keeping it fast. Major Russell, advocates the general use of some such means, as he asserts, and truly so, that it is desirable in all dry processes.

Now, it is a simple fact, and that without any qualification, that no preservative substances whatever are required: good pictures can be got without them. If the film be excited in the ordinary way, well washed and dried, it will be found sensitive still, and as sensitive as the best of any other dry process. More than this, it will be found perfectly easy to develop the picture. It comes out quickly and with ease, and is perfectly under command. The results will be found very similar to those which would be obtained with the same collodion in a wet state, except that there is a slight loss of intensity. If a small quantity of common resin—say half-a-grain or a grain to the ounce—be previously added to the collodion the intensity will be very materially increased, and for transparent positives a very beautiful colour will be obtained.

One great point, I find, is to keep the sensitising bath very acid with *acetic acid*. The only other precaution is to adopt some means of keeping the film on the plate. This may be done either by painting the edge with varnish or covering the surface with gelatine or albumen. I much prefer albumen. I simply add the white of an egg to eight ounces of water, with about half-a-drachm of glacial acetic acid, shake the whole well together in a bottle, let it stand a few hours, filter it, and bottle it for use. The quantity is sufficient for a very long time, as it is simply poured on and off again into the bottle—if necessary, helping it to spread with a glass rod. The plate is then dried before a brisk fire, put by to cool, and then the ordinary manipulation is followed.

I prefer washing in a series of dishes, pouring over the plate, when taken from the last dish, a gentle stream of water to remove any particles which may have settled upon it. The plate is then dried spontaneously, and stored away for use.

I have tried several sorts of collodion, and find the same especial results. The qualities of each sample come out on the dried plate in the same way in which they are apparent in the wet state.

Let it be understood I claim nothing as new. I only know that, after years of labour and failures, I have at length

* Read at a meeting of the North London Photographic Association, November 20th, 1861

found a method of getting pictures which supply my wants. I know beforehand that if I can get a good picture with the collodion in a wet state, that I shall get the same results, or even better, in a dry condition. I speak advisedly when I say *better* results; for the amount of detail which I have thus got in my dry negatives could never be obtained with the same material in a soft spongy condition.

Dictionary of Photography.*

Sandarac.—A resin which forms the basis of most spirit varnishes. It is sold in small yellowish brown drops, called "tears," and is entirely soluble in alcohol. In combination with shellac it forms an excellent spirit varnish for negatives.

Sea Water.—Containing all the salts which by combination with silver form sensitive compounds, it is not surprising that sea-water should have been suggested for preparing paper instead of the ordinary salting solutions. The proposition has never been carried into effect to any extent, nor with any palpable advantage, one of the chief difficulties consisting in the fact that sea water is an uncertain and variable compound, a variety of local causes affecting its exact composition. The analysis of the water of the English Channel, as conducted by Dr. Schweitzer, of Brighton is as follows:

1000 grains contain—

Water	964·745
Chloride of sodium	27·059
" potassium	0·766
" magnesium	3·666
Bromide of do.	0·029
Sulphate of magnesia	2·296
" lime	1·406
Carbonate of do.	0·033
Traces of iodine and ammoniacal salt	
	1000·000

Sel d'or.—The double hyposulphite of gold and soda, used for gilding Daguerreotypes, and in some toning processes, for paper prints. The solution is formed by dissolving one grain of chloride of gold in an ounce of water, and three grains of hyposulphite of soda in another ounce of water, and then mixing the two. Great care is required in this operation: the solution of gold must be added to the solution of hyposulphite of soda, stirring the solution at the same time. If the contrary course were followed, and the hyposulphite solution added to the gold, the latter would be at once precipitated. Sometimes the proportion of four parts of hyposulphite of soda is added to one of gold. The commercial sel d'or is sold in white needle-like crystals; it is precipitated from the solution above described, by the addition of alcohol. Commercial samples are often largely adulterated.

In the Daguerreotype process, the plate, after fixing with hyposulphite of soda and well washing, is covered with the solution of sel d'or, and the flame of a spirit lamp applied underneath. In a short time the plate is covered with small bubbles: it not unfrequently happens that the plate at first begins to assume a clouded appearance, but on the continued application of heat all this disappears, and the picture assumes a richness, brilliance, depth, and purity of tone far superior to what it possessed before. It is then to be rinsed with distilled water, and dried carefully by the aid of the flame of the spirit lamp. Care should be used not to apply too great a heat, nor continue it too long, as exfoliation, or the cracking and flying up of the deposited layer of gold in thin leaves may ensue. This process of gilding is not only a great improvement to the appearance, but affords an effectual protection to the picture.

The sel d'or toning process for positive prints is chiefly applicable to plain paper, and is not usually successful when applied to albumenized paper. The prints are to be immersed in a solution containing one grain of sel d'or to five ounces of water, or, if made impromptu, two ounces of the solution above described added to sufficient water to make a pint. A few drops of hydrochloric acid are generally added. The time of immersion will be regulated by the tone required, but a few minutes will generally suffice. When deep enough the print is to be thoroughly washed in several changes of water to remove all trace of acidity, and then fixed in fresh hypo. The sel d'or bath should not be used again. This bath is still used by some operators, but is gradually being superseded by the alkaline gold toning process. It is maintained by some that the sel d'or process does not necessarily involve any sulphur toning action, and that if properly conducted the prints are perfectly permanent. It is a safe precaution to wash the prints in a water slightly alkaline before immersing in the fixing bath, and by that means preventing the danger of leaving any trace of acid which might decompose the hyposulphite of soda.

Sepia.—A rich warm brown pigment, obtained from a secretion of the cuttle-fish. Drawings in monochrome with this pigment used to be much in vogue. The tint is an excellent one for photographers, especially landscape photographers, to aim at in toning their prints. The pigment is valuable for "re-touching" photographs.

Serum of Milk.—This substance has been proposed for, and used in, several photographic processes. It has been used in connection with the salting bath for plain paper, in order to retain the silver on the surface and give vigour to the print. It has also been proposed as a preservative to the collodion plate in the Fothergill process, in place of the albumen solution. It is procured by adding a little rennet to skimmed milk, and allowing it to stand in a warm place. The curd is then removed, and the resulting whey or serum preserved for use. It is more generally procured for photographic purposes by adding lemon juice to skimmed milk. A tablespoonful of lemon juice is added to a pint of the milk, which is boiled, and then strained to separate the curd. To the liquid thus obtained the desired portion of chloride is added, and the solution used for salting the paper. Mr. Sutton, who has frequently advocated the use of serum of milk for this purpose, says it gives richer blacks and purer whites than any other similar preparation.

* Continued from p. 474.

A FEW WORDS ABOUT PHOTOGRAPHY.*

Of all the delights that science has bestowed upon mankind, surely the most charming is photography, in its varied phases and universal range! The wonders and pleasures of the telescope and microscope are restricted to a comparatively limited number, and require more or less of scientific education rightly to appreciate their marvels. Photography, with a more liberal hand, bestows its treasures on all comers —from the learned Professor, gloating over the exquisite delineations of glaciers from the remotest valleys of the Alps, or the geological strata of some cliff face in Central Africa, which the labours of enterprising photographers have laid on his library table—to Private Jones of the Militia, who exchanges portraits (price 6d. coloured, frame and glass included) with the maid-of-all-work who has captivated his martial soul. Is not this a popular science.

From the conquests already achieved by this young child of science, it is difficult to assign any limits to the range of photography. Some one has lately been taking photographs at the bottom of the sea, so that we may shortly have a "Gallery of Portraits of Remarkable Fishes," taken at their own marine residences; and, on the other hand, photographic portraits of the moon have long been familiar to us, and have had the effect of correcting the erroneous impressions formerly entertained of the personal appearance of that much esteemed luminary, derived from public-house signs and children's picture-books, by no means flattering in point of beauty, nor correct in a scientific sense. Granting, therefore, that it is a long way from the moon to the

* From the *National Magazine*.

bottom of the sea, our position that the range of photography is somewhat extensive will be readily admitted; and, by the aid of the balloon in one direction, and the diving-bell in the other, fresh discoveries may be constantly expected.

Very rapid, certainly, has been the progress of photography. We can all remember the wonder and delight with which the early efforts of Fox-Talbot, Daguerre, and others were welcomed; and we have a very vivid recollection of those extra-*ordinary* portraits, about two inches square, at a guinea each, that could only be seen with great difficulty in one particular light, and then were so hideously ugly that you felt rather thankful that they were mostly invisible. Now, what with "Pistolgrams of Babies," *Cartes de visite*, &c., &c., &c., a man is fortunate who escapes with having his likeness taken not more than once a year: and as for remarkable persons about whose *physique* the public are solicitous, they must spend a considerable portion of their lives in undergoing this pleasing operation; and we suppose they are waylaid on all occasions, and dragged off to the dens of photographers, and there, with a pistol at their heads, compelled to put on their most benevolent aspect for the process.

Science has great cause for gratitude for the perfect records of her operations supplied by photography, and the camera and its apparatus are now considered indispensable to scientific expeditions. On the occasion of the total eclipse of the sun, the year before last, when the gigantic *Himalaya* loaded a "full and complete cargo" of philosophers to proceed to Spain to witness the eclipse from the central point, great preparations were made for recording the various phenomena by means of photography, and marvellous and beautiful were the results obtained.

Commerce, too, makes large demands on the services of photography. House-agents give you pretty views of the houses they have to dispose of; machine-makers, engine-builders, sculptors, and many others who require accurate delineations, now substitute photography for any other kind of drawing. For presenting a faithful record of the progress of large works it is invaluable. We were, a few days ago, in the office of one of our large contractors, who is making a railway in some remote portion of the globe, and, wishing to refer to some part of the works, he whistled and grunted through a flexible tube that hung at his elbow, and a clerk appeared with a huge book, which appeared to be full of photographs of the works on the line, pasted two on a page, the dates attached to each, forming a complete and accurate record of the progress of the works. Very beautiful photographs they were, and very curious in the minuteness of the detail: better than any series of reports were these pictures, unimpeachable in their integrity. It was no use Mr. Resident Engineer describing all things going on swimmingly, when the photographs accompanying his letter shewed an ugly swamp which swallowed up their earthworks as fast as they were made, shewing weeks of fruitless labour: quite useless to report that such a station was finished, or such a bridge completed, whilst the incorruptible camera told a different tale. We found it was now a very usual practice for a photographer to accompany the staff on works of any magnitude.

So much for the useful; but what shall we say for the beautiful? Adjectives fail us. Look at those beautiful pictures of Bissons Frères, of Alpine scenery, giving the very texture of the snow, sullied by the summer thaw, and furrowed by the fierce blasts that sweep the ravines, and assist the sun to free those cold, dark peaks of granite, from their winter thraldom. How hard and defiant they look during their short escape! There is absolute sublimity in these small pictures, from their unerring truthfulness, which no painting or description can approach. Or those equally magnificent Egyptian scenes of Frith's, where you seem to feel the intense heat of the sun that casts that sharp black shadow from colossal gateway or ruined porch, over the burning sand, and admire the enthusiasm that led Mr. Frith over those hideous wastes of sand and granite, where the photographic tent became an oven in temperature, and the "collodion boiled upon the plates." And for the result of his labours, we have on our drawing-room tables a handsome volume of the ruined treasures of Ancient Egypt and the Upper Nile—the mountain scenery and the noble cedars of Lebanon, and the crags and peaks of Sinai and Ararat. Then, again, we have those lovely sea-pieces of Gustave Le Gray, where the curl of the breaking wave, or the shadow of the passing cloud, have been arrested by the instantaneous magic of the camera, and presented before us, in such wondrous beauty. Then Roger Fenton and many others spend their summer days (and what a charming life it must be!) amongst the choicest nooks and corners of English scenery, and their lovely pictures are scattered broadcast over the land.

Architecture, too, draws largely on the science; and Rome and Venice, Florence and Verona, Rouen and Amiens, Ghent, Brussels, Cologne and Heidelburg send us charming pictures of their great masterpieces; whilst in our own country there is scarcely church or castle, tower or hall, of any pretensions to architectural merit or picturesque beauty, that has not been made familiar to us by photography. And what a pleasure there is in these pictures—what a charm in the feeling of their absolute truth and of their completeness! You can take a powerful magnifying glass and examine a first-class photograph, say of an old Italian cathedral, till you can see the moss and lichen, and the fantastic tooth-marks of old Time on the gateway stones; or, in the interior, detect the dark circle round the font, or the path to the high altar, worn by the countless steps of many generations of pilgrims. All that the original contained *is there* if you could only see it, and the beauties of a fine photograph continually increase on examination, and every effect of light and shade, atmosphere, perspective, and even chiaroscuro, are represented with a fidelity of effect that in many points leaves all painting at an unapproachable distance.

AFFINITY OF IODINE, BROMINE, AND CHLORINE FOR SILVER.

BY FREDERIC FIELD.*

Although both bromide and iodide of silver are decomposed by the action of chlorine at an elevated temperature, yet chloride of silver is completely decomposed by bromide of potassium, and both the bromide and chloride of silver by iodide of potassium. Even the action of hot strong hydrochloric acid has but little influence upon the iodide of silver; many days of continuous boiling are necessary for its entire decomposition. I believe that it has been the opinion of chemists that chlorine possesses an affinity for silver superior to all other elementary bodies, and we are told in Gmelin's Handbook that all salts of silver, even the insoluble ones, are converted into chloride by solutions of metallic chlorides. From the following experiments it appears to me that bromine has a greater affinity for silver than chlorine, and iodine a still greater affinity than bromine.

When a mixed solution of bromide of potassium and chloride of sodium is added gradually to a solution of nitrate of silver, not in excess, no trace of chloride of silver is precipitated, as long as any bromide remains in solution.

If to a similar solution, iodide and bromide of potassium and chloride of sodium be added, iodide of silver and nitrate of potassa are formed, the bromide of potassium and of chloride sodium remaining undecomposed.

When bromide of potassium is poured upon chloride of silver, an entire decomposition ensues, bromide of silver and chloride of potassium being produced.

When iodide of potassium is added to chloride of silver, iodide of silver and chloride of potassium are formed; and when iodide of potassium is added to bromide of silver, there is a similar decomposition, the iodine replacing the bromine.

When chloride of silver in excess is agitated with a solution

* "On the Separation of Iodine, Bromine, and Chlorine, and the Comparative degree of Affinity of these Elements for Silver; with some Analyses of their Combinations with that Metal occurring in Chili." By Frederic Field, Esq. Communicated by Dr. Hofmann, F.R.S., to the Royal Society.

of iodide of potassium and warmed for some hours, no trace of iodine can be detected in the solution: when, however, chloride of sodium is poured upon iodide of silver, no decomposition occurs, neither is there any action upon bromide of silver with the same salt: and when bromide of potassium is added to iodide of silver, there is no alteration in the union of the elements.

From a number of experiments made in illustration of the preceding statements, I deemed it possible that the separation of chlorine, bromine, and iodine, could be accomplished by this reaction.

The method which I have devised is simply this:—After weighing three equal portions of the salts to be analysed, they are placed in three flasks, with ground-glass stoppers, and about an ounce of water is added to each; nitrate of silver being then added, slightly in excess, to the three, the stoppers are replaced, and each flask agitated violently. The precipitates subside in a few minutes, leaving the supernatant liquid perfectly clear. They are then filtered through separate funnels, and washed with hot water. No. 1 is dried and weighed. No. 2 is digested in bromide of potassium, dried, and weighed; and No. 3 in iodide of potassium, dried and weighed.

To test the method, a mixture was made of 5 grains of iodide of potassium, 5 grains of bromide of potassium, and 5 grains of chloride of sodium. The following is a comparison of the theoretical and experimental results:—

	Experiment.	Theory.
Iodine	3·69	3·81
Bromine	3·51	3·34
Chlorine	2·92	3·02

I have availed myself of this method in analysing several silver ores containing chloride, bromide, and iodide of silver found in Chili, the formulæ of which I subjoin:—

Chloride of silver	... Ag Cl.
Chlorobromide of silver ...	... 2Ag Cl, AgBr.
Chlorobromide of silver ...	... 3Ag Cl, 2 AgBr.
Chlorobromide of silver ...	... Ag Cl, 3 AgBr.
Bromide of silver	... Ag Br.
Iodide of silver	... Ag I.

Proceedings of Societies.

London Photographic Society.

The usual monthly meeting of this society was held on the evening of Tuesday, December 3rd, Henry White, Esq., in the chair.

The minutes of a previous meeting having been read and confirmed, the following gentlemen were elected members of the Society:—Messrs. Greenwood, Cole, Tant, Montefiore, Hewitt, and Castleman.

The Chairman said in accordance with the seventh rule of the society, he would now read the names of the retiring officers, and those nominated by the Council for election in their places at the annual meeting to be held in February. Should any member desire to propose other gentlemen for election it would be necessary to do so at, or previous to, the next meeting to be held in January. The retiring Vice-President was Professor Bell, and Mr. F. Bedford was nominated by the Council as his successor. The members of the Council retiring were Messrs. Crace, Maskelyne, Stokes, Delamotte, Bedford, and Dr. Fane; in their places the following gentlemen were nominated:—Messrs. D. Wright, Vernon Heath, Glaisher, Joubert, H. P. Robinson, and Professor Sedgwick.

The Secretary then read a letter received from Mr. Brown, Secretary of the Birmingham Photographic Society as follows:—

"*Birmingham Photographic Society, Dec.*, 2, 1861.

"Dear Sir,—I intended being present at your meeting tomorrow evening, with some of Mr. Breese's stereograms, particularly his views of the moon, but at the last moment am prevented. I should have been more annoyed at this delay, but I hope ere another meeting of the Society to be enabled to lay before the members a view, or views, of the moon taken either by myself, aided, of course, by the appliances of Mr. Breese, or by Mr. Breese in my presence. Although I have no doubt in my own mind that the pictures are what it is pretended they are, viz., views of the moon and clouds, taken by the light of the moon at midnight. In one case through an open window of a room, at which sits a lady whose features are not more than a silhouette, though the lace sleeve, and ornaments upon the table, upon which she rests her arm are distinctly rendered in every detail. Still I wish to remove any shadow of suspicion that may attach to Mr. Breese in consequence of his being so backward in explaining the means by which he produced them; but when I tell you that he is an amateur, and has spent a very large amount both of time and money in bringing his ideas to perfection (though he does not so think them), I do not think that he is called upon to lay his ideas before the world without any recompense. He has a very strong objection to give any explanation whatever until he has completed his experiments, and this is the main ground for his remaining so quiet upon the subject, coupled with his generally unobtrusive manner. The question of their being instantaneous I have disposed of in my reply in the *British Journal* to the remarks of Mr. Cramb, of Glasgow. Regretting not being able to make your acquaintance to-morrow evening, I am yours faithfully,

"Jno. T. Brown, *Hon. Sec.*

"H. Diamond, Esq., M.D."

Mr. Vernon Heath wished to put two short questions to the Chairman which he had no doubt would be very easily answered. One had reference to an answer in the last number of the society's *Journal*, regarding the annual exhibition of the society. He thought desirable that it should be distinctly understood whether the ordinary exhibition of the society would be held at the commencement of next year or not. His second question had reference to the International Exhibition to be held next year. He thought the time had come when they ought to know definitely what had been done by the society in reference to this matter; and in what position photographers would stand in relation to the Great Exhibition of 1862.

The Secretary said, the Council had considered the subject of their ordinary annual exhibition, and had come to the conclusion that no such exhibition should be held in the coming year (hear, hear). Regarding the International Exhibition of 1862, the members of the society were already familiar with the correspondence and its results. Since then the Commissioners had sent circulars to various gentlemen, asking them to act in a committee for the management of the photographic department. He (Dr. Diamond) had received one of those circulars, and had at once waited upon the Chief Baron, and taken his advice on the subject as to how he should act. The Chief Baron asked, with whom he was to be associated, and on learning, he stated that he thought it was desirable—now that the society had made their protest against what they conceived was an improper classification—that they should aid the exhibition to the best of their ability (hear, hear). He might now announce therefore that the committee would be formed by the Earl of Caithness, Mr. Kater, and himself (Dr. Diamond), and that Mr. Le Neve Foster would be the superintendent.

Mr. Heath asked if these gentlemen constituted the whole of the committee, or merely all as yet appointed.

The Secretary believed that it was complete.

Mr. Heath said as it was now too late to discuss what ought to have been done, but since a committee was appointed, he thought that photographers generally should give the best aid they could in any way; and if it was still thought desirable to add to the number of the committee, the best persons from other societies, as well as this, might be induced to act, so as to secure to photography the best possible representation, and all pull together for a successful result at the coming Exhibition.

The Chairman remarked that there were 250 applications for space in the photographic department; and 2,400 square feet of space applied for.

Mr. Heath understood that 2,300 square feet were applied for by one person.

The Secretary remarked that that application was for counter room to exhibit apparatus.

Mr. T. Ross then read a paper on the panoramic lens. At the termination of which he exhibited the apparatus and showed a number of very fine negatives; one of his assistants also showed the facility with which curved plates could be coated with collodion.

The Chairman asked if it was possible to flatten the glass after the negative was taken, and so print from it flat.

Mr. Ross did not think it could be done, nor did he think it was necessary. If the chairman would examine the printing frame provided he would see that the printing was very easy. It had been suggested that the film might be removed so as to print from it when flat.

The Chairman remarked that removing the film was a difficult and a dangerous operation. He asked Mr. Bedford's opinion of the apparatus.

Mr. Bedford said this was the first time he had seen it.

Mr. Ross stated, in answer to a question, that the glasses exhibited, 9 by 5, were 18s. a dozen.

Mr. Shadbolt then read a paper on washing prints, in which he urged the importance of draining the prints thoroughly between each washing, so as to get rid, each time, of as much as possible of the former water, and thus avoid adding dilute hypo to each fresh dish of water.

Mr. Vernon Heath said he was happy, without knowing anything previously of Mr. Shadbolt's views in this matter, to be able, in all respects, to confirm his remarks, and to concur most heartily in the statements regarding the advantages of such a mode of washing. He would be happy to show any gentleman who might wish it, the system in operation. It was, he conceived, founded on reason, it proved most efficient in practice, and he believed it was an actual saving of time. He used the American clips which Mr. Shadbolt had referred to. Betwixt each change the print was laid on a plate of glass, which was placed under a tap at angle of 45° and well washed. The water in which they were placed was changed every ten minutes, and they were left to drain, between each washing, for twenty minutes. By that time the draining was very complete, so that the print contained no more of the washing water than just kept it damp. He believed that three or four hours washing of this kind would be much more efficient in removing all traces of the hyposulphite than any number of hours in which the changes of water were made without these precautions. A gentleman had that day told him of a plan he adopted; he had a large perforated box made for the prints, and this was sunk in a river, so that the stream might continually pass through. It was his (Mr. Heath's) opinion that this would be altogether inefficient, as the prints sticking together would effectually prevent perfect washing. He believed if the plan of perfect draining between each washing were tried, it would be found that the trouble was really less, whilst the results were incomparably more satisfactory.

Mr. S. Davis referred to the method, which he practised, of washing the prints when they have left the printing-frame, which was similar in principle. Instead of immersing the print in the water, he merely laid it upon it, so that the free nitrate of silver was gradually dissolved and dropped down into the water. He found that the free nitrate might thus be removed from the print much more readily than by any other method.

Mr. Martin said it had occurred to him whilst listening to Mr. Shadbolt's remarks on the importance of getting rid of the hyposulphite, and the difficulty of finding a sufficiently delicate test to decide when it was all removed, that the addition of acid to the final washing water, followed by the nitro-prusside of sodium would produce a very definite reaction if sulphur were present. He referred to Mr. Williams as to how far this might be regarded as a satisfactory test.

Mr. Williams said the nitro-prusside of sodium was a test only for sulphides.

Mr. Martin said he had suggested the addition of acid for decomposing any hyposulphite, and liberating free sulphur.

Mr. Williams said this would not produce a sulphide, and the test was valueless otherwise. He might here mention a plan of washing, which was adopted by one gentleman very successfully. The prints after each washing were placed between clean blotting paper, and then subjected to a heavy pressure with rollers, which squeezed every drop of moisture out of them. Three repetitions of this treatment was considered sufficient, and better than a week's washing without such treatment.

The Chairman thought that this would be a somewhat expensive method, as the blotting paper could not be used for the same purpose twice.

The Secretary referred to the spoiling of some prints from the accidental use of blotting paper, which had served such a purpose. He remembered that Count Montizon, whose pictures, he believed, had generally turned out permanent, was in the habit of laying his pictures on plate glass during the process of washing, and between each water dab them with a tuft of cotton wool until they were dry.

The Chairman expressed a conviction that it was not always imperfect washing which caused prints to fade, but some action which was set up in the fixing bath. He did not think, therefore, that a trace of hyposulphite of soda, left on the print, would necessarily cause fading.

Mr. Shadbolt said it was not hyposulphite of soda, so much so as hyposulphite of silver, in the print, the decomposition of which was the cause of yellowness and fading.

After the usual votes of thanks the meeting terminated.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 4th December, 1861.

M. Baudrimont gives, as the result of his researches upon the chemical action of solar light, that—contrary to the opinion generally entertained—chemical rays exist throughout the whole extent of the solar spectrum. The facts observed also lead to the belief, that each species of coloured light possesses a special action, and that each may be completely inert with regard to certain matters; but, on the contrary, very energetic with respect to others. Another series of experiments enables M. Baudrimont to establish the influence of the various colours of the spectrum upon the development of vegetation. Thus, for instance, no coloured light permits vegetables to go through all the phases of their evolutions; none of them have flowered or fructified. Violet coloured light is positively injurious to plants: they absolutely require white light.

M. Béchamp has published a summary of his researches upon xyloïdine, and upon some of the new nitric compounds of fecula. He shows that the xyloïdine of Braconnot is a mononitric derivative of fecula: that the latter can engender a second nitric combination richer than the first in nitric acid; that all these products can regenerate soluble fecula, and that we must regard them as combinations in which the molecule of fecula is united to molecules of nitric acid in the same ratio as in nitric ether or in nitrate of potash.

A very important fact in connection with sanitary science and with physical geography has been made by the illustrious agricultural chemist, Boussingault. He lately read before the Academy of Sciences a paper in which he demonstrated, with remarkable precision, that oxide of carbon accompanies the liberated oxygen, whenever the sun shines upon a vegetable submerged in water impregnated with carbonic acid. The presence of so deleterious a gas as carbonic oxide in the atmosphere of marshy countries is manifested by this discovery, and it explains the fatal attacks which animals suffer in the health when exposed to the influence of marshy exhalations.

On the other hand, it is maintained, that in large cities were coal is consumed, as in Paris and London, carbonic oxide is much more abundant in the atmosphere than it is in the most unhealthy marshy situations, and yet marsh fevers do not prevail in those cities. This has led to the conclusion that the cause of marsh fevers is due to a solid organic body, a microscopic insect, or the *débris* of an insect carried through, and penetrating the air-passages of, the lungs, and acting like a putrid foreign body which vitiates the whole mass of the blood in the animal by a process of putrefactive fermentation.

M. Ville, who has for some time past been carrying on a series of elaborate investigations upon the efficacy of certain soils upon the development of plants, measures the results with mathematical precision by means of photography in the following manner:—When two or more plants sown upon the same day, but developed under the influence of different fertilizing agents, have arrived at a certain stage of growth, M. Ville takes photographs of them upon the plate which at the same time gives copies of a scale composed of squares, each one decimetre in length and breadth, against which each plant measures itself; thus, at the first inspection of the photographs, it is easy to arrive at an exact appreciation of the superiority of one fertilizing agent over another.

The use of albumen, or whites of eggs, has been greatly extended in the arts of late years, but as only a moderate demand existed for the yolks, it has been the subject of much interesting inquiry to know how to dispose of them profitably. M. Edmond Sichel has suggested a useful application of the yolk of egg. The first step was to find a solvent for it: after many researches, glycerine was found to possess the desired properties. Yolk of egg dissolved in it yields a limpid yellow liquid. This solution has received the name of *glyconine*, and is found useful in medicine, replacing the oil of eggs (a preparation very difficult to form), employed for scratches and excoriations. The yolk of egg is concentrated by endosmose; it is put into a bladder, which is placed in a vessel containing a supersaturated solution of salt: in the course of a few days it is deprived of its water.

M. Dubois, one of our most eminent photographers, renowned for his excellent glass postives, has brought into notice a method of obtaining pictures on varnished cardboard, invented by M. Merricune, which advantageously replaces silver plate and glass plates in positive photography.

First, as to the nature of these new plates; they consist simply of thin and flexible cardboard, covered with several coats of hard black varnish, smoothed and polished by the ordinary methods employed by carriage builders and others. This manufacture is capable of being carried to great perfection: but already card plates are produced which are impervious to moisture, unacted upon by the several photographic solutions, susceptible of receiving all the necessary preparations, and upon which the collodion spreads with the greatest facility. The chief merit of these cards consist in their taking an extremely fine polish, from whence results a harmony of tones in the proofs, with a vigour and sharpness unattainable upon glass or paper. The cost of these new plates is inconsiderable, and their manufacture is undertaken on a scale sufficiently extensive to supply any reasonable demand; and thus we have at command a useful process, from which skilled operators may derive considerable advantage.

The method of operating with these varnished cards is exactly the same as that adopted for glass positives. The card plates are collodioned, sensitized, and exposed, then developed with a solution of iron, and fixed in the usual manner.

The superior lightness of the varnished card over glass will recommend it to the attention of the travelling photographer. Instead of obtaining uncertain negatives on glass, he will prefer to obtain a perfect positive of a view on the spot; for if an imperfect result should arrive, the work can be recommenced immediately upon the same card; for by passing a sponge over it, everything is removed. If subsequently it is found desirable to multiply copies of this positive, nothing can be easier, as it may be copied as readily as a picture or an engraving.

When the positive proof obtained upon the varnished cardboard is completely dry, it is perfectly solid: it would be necessary to scratch the surface, so as to remove the varnish, to efface the picture. Thus the fear of accident by breaking the glass through clumsiness or accident, to the ruin of the prized work of art, no longer need exist; the card may be bent without breaking, and this is certainly not the least of its recommendations. There is, however, another which is worthy of notice, the pictures on cards can be cut to fit into brooches, rings, &c.

But, perhaps, the chief merit presented in the new method is the perfect delicacy of detail in the image, the sharpness of the outline, and the transparency in the shadows, seldom, if ever, attained in pictures on glass: thus they possess all the delicate qualities so much admired in the Daguerreotype, without the intolerable mirror-like reflection of the latter.

By the convenience of transport, lightness of material, the rapidity of the operations, and the facility with which proofs can be taken during travelling, this process is particularly applicable to military photography, and will, doubtless, be largely applied on future occasions of reconnoitering.

The success of this method, as we have before stated, will depend upon the fineness of the polish given to the surface of the cards. As this can hardly be accomplished by hand, the mechanical polishing machine invented by M. Richardin will render the desired service.

[If we rightly understand our Paris correspondent, there is nothing new in this invention of M. Dubois. Several similar methods have been practised; and the "Niellotype" of the American operators appears to be identical with the process now described.—Ed.]

TONING AFTER FIXATION.

Sir,—When lately in Paris, I asked at M. E. Chevalier's, for the latest work on photography which had been published there. A small volume of the "Encyclopedie-Roret," was given to me. It is by M. E. de Valicourt. I have not had time to examine more than his directions for printing; they differ so much from the system adopted in this country that I think it may be interesting to give a summary of them. They are as follows:—

1. After exposure wash well, keeping the print in movement.
2. Fix in hyposulphite of soda—75 to 500 of water—leave it in from fifteen to twenty minutes.
3. Wash thoroughly so as to remove completely all trace of hypo.
4. Tone in a bath of neutral chloride of gold—1 to 800 of water—he states that after an immersion of some minutes the print becomes a deep red, then dark brown, and at last an intense dark violet.
5. Wash, &c.

I have never tried the system of fixing and thoroughly washing a print before toning, therefore offer no opinion on M. de Valicourt's recommendations, but if they are correct, they give this advantage. You will be certain of the ultimate colour of your print. Whereas under the system, as recommended by you, and I think all our English writers on photography, viz., toning first, and then fixing, there is always some uncertainty. It is difficult to retain the beautiful tone of the print, as it leaves the toning bath, after a sufficient immersion in the hyposulphite.—I am, sir, your obedient servant, N.

November 30th, 1861.

[If the toning of prints could be conducted successfully after fixation, some trouble and vexation would be avoided. Some years ago we made some experiments in this direction, but without very satisfactory result. We found it was almost impossible to tone an albumenized print at all after fixing. Fixed prints on plain paper were toned with less trouble, but a very strong gold solution and somewhat prolonged immersion was necessary. We are now speaking from memory, as the notes made on the subject are not at hand; but we came to the conclusion that the advantages were not at all commensurate with the trouble. Probably M. Valicourt refers to prints on plain paper. Regarding the loss of colour in the fixing bath, we know many first-rate photographers who tone with the alkaline gold bath, are in the habit of adding a little neutral chloride of gold to the hypo bath, to satisfy, as it were, its appetite for gold, and prevent it attacking the tone of the print. This is very like using hyposulphite of gold. It is argued that when the bath has toned a few prints the result is the same as if gold were added direct. After all that has been written on the subject of printing, toning, and fixing it is in a sad state of uncertainty.—Ed.]

A SUGGESTION FOR SECURING PERMANENCY.

Sir,—I have received the following statement from so trustworthy a source that I have no doubt of its accuracy.

Captain H—— returned from India, a short time ago, bringing with him a collection of photographic views taken there by himself.

My informant, himself a good photographer, assures me, that although they have been carelessly kept—much exposed to light and damp—the prints retain all their original freshness and purity of colour; yet they were taken and printed under great difficulties. The station, where Captain H. was quartered, was in some part of India where the heat in his tent was so intense, that the mercury in the thermometer used to rise to ——! I fear to repeat the number of degrees mentioned to me; but it certainly represented an amount of heat greater than I should have supposed it possible for an European to bear.

But this was not his only difficulty. There was an almost absolute want of water, so that, after fixing and toning his prints, he could only steep them for an hour or so in the smallest quantity of water which he could afford for this purpose, he then hung them up in his tent to dry, and, I am told, took no farther trouble about them, yet they have remained to this day, I believe over eighteen months, fresh and perfect in colour; I wish I could say as much for my best prepared and best washed prints, nay, even for some in my possession done by our best artists.

May not a lesson be learned from the above statement? Sulphur volatilizes at 180°.

Has exposure of the print, after toning and washing, to a dry heat (say about 180°) ever been tried, as a preservative against fading and change of colour.

Perhaps light and heat combined may be required? a glass case may be so arranged as to represent, to a certain extent, an Indian tent in light and heat.

Perhaps, also, "time" may be of great importance in trying the experiment?—I am, your obedient servant, N.

Photographic Notes and Queries.

Splitting of the Collodion Film.

Sir,—In your notice of my former communication on the above subject, you complained that I was scarcely logical, and I admit that on reading my note again, you had some reason for your opinion.

Since I made you that communication I have found the statement to which I have referred, and as it is by no less an authority than the late Editor of your journal, a gentleman whose opinions on matters connected with chemistry I believe ranks very high. I send it you for the information of your readers. In Vol. iv., page 60, of the Photographic News, in reply to a correspondent, "W. L. C.," he says:—"Too much bromide will act mechanically, causing the film to tear;" also, in the same column, in reply to another correspondent, "Collodion," he states that "too much iodide or too much alcohol will cause the film to slip off when washed. The remedy is more pyroxyline or ether, &c." Thus showing that the authority quoted does believe in the fault arising in some cases from the nature of the sensitizing compounds. Of course, I am aware that these opinions may be mistaken ones; but as editors of Scientific journals are always supposed to be thoroughly conversant with the subjects on which they write—in fact, are teachers of a high class—one naturally considers their opinions worth attention until they are disproved.

I may add to the former notice of my difficulty in this way, that the film showed symptoms of its disposition to split up, on removal from the sensitizing bath, therefore, it could not be from developer or fixer. I cleaned the plates with unusual care after the first failure, and therefore consider the difficulty lay between bath and collodion; but in the case of "A Perplexed Amateur," one would scarcely refer it to the collodion, as he states that several collodions act in the same way in his case. And as he also states that he finds it occur in the wet process, it can scarcely be the preservative agents. May not his difficulty lie in some peculiar condition of his sensitizing bath? would it not be as well to try the collodions, &c., with another bath? I must apologize for troubling you again on on this subject, the importance of the matter to all who practise the beautiful art of photography, I trust will be found a sufficient excuse.—I am, sir, yours respectfully, E. E. L.

P.S.—I would ask your talented correspondents who suggest various additions to, and substitutes for the preservative agent to consider how they would treat such a case if working with wet collodion only? As in this, I think, will be found the solution of the difficulty.

[In referring the advice, which you quote, to the "late editor," "whose opinion" &c., you doubtless allude to Mr. Crookes, and your remark regarding the value of his opinion on matters connected with chemistry, we have pleasure in fully endorsing. You are in error, however, in your conjecture. Mr. Crookes had ceased to conduct the News at that time, and is not responsible for the opinion quoted. As there was an interregnum between the retirement of that gentleman and our own acceptance of the duties, we are uncertain as to the author of the advice. It was doubtless, however, conscientiously given, and based on some grounds. We cannot, however, indorse either statement. We have not found, in the course of very considerable experiments in the manufacture of collodion, that bromides, in much greater proportion than they are generally used, exercise any mechanical effect on the film. And regarding excess of alcohol, we should rather consider it as an adjunct to the preservation of the film, than as a cause of splitting, provided always that the film was allowed to set sufficiently before immersion. There are two or three prolific causes of splitting films in both wet and dry processes. The most common is the use of imperfectly cleaned or damp glasses; the next, immersion before the film is well and evenly set; the next, is under-exposure and prolonged development; the next, an imperfect sample of pyroxyline; the next, too much water in the collodion. An acid bath may aid some of these causes, but will not, we think, produce the effect alone. Other causes, as have been suggested, may operate; but in the wet process we believe, these are the chief causes, and their frequency of occurrence will be found in the order in which we have stated them. If the glass be perfectly clean and dry, the film properly set, and the exposure sufficient, even where the other causes are present, the films will very rarely split.—Ed.]

Dear Sir,—Through a mistake, the News was mislaid, so that I was debarred the pleasure of the perusal of its contents till this evening, and I hasten to inform your correspondent, "A Perplexed Amateur," if he will make a thin solution of gum arabic, and pour over the plate after fixing and washing, he will no longer have cause to complain of his films splitting. I practise the tannin process, and am perfectly satisfied with the same, being the most simple, *and, in my hands,* the most successful. Since using the gum solution, as recommended by Mr. Sutton in his "Notes," I have never lost a negative from the film splitting, I also use it after intensifying, and can dry my negatives by the fire and varnish them off at once, without distorting my features from fear of seeing the film part company with the glass.

Have you or any of your correspondents tried alcohol and acetic acid for cleaning glasses, if not, you will not regret the trial.—I am, sir, yours obediently. J. Drake.

Printing and Toning.

Sir,—As you did me the honour of inserting in your last week's News a receipt for mauve toned prints, I now give my *modus operandi* for printing on albumenized paper. I sensitize on a 30 to 60-grain solution of nitrate of silver, six to twelve minutes, according to strength of bath. Slightly over print and remove to bath No. 1, composed of

Soda acetate	4 drachms
Water	10 oz.

Allow the print to remain at least ten minutes, to convert all free silver into acetate of silver; and then slightly wash and place in toning bath No. 2.

Gold chlor....	4 grains
Soda acetate	4 drachms
Water distilled	10 oz.

This bath must be made at least 24 hours before use, and will keep any length of time. Tone to a rich purple, and fix in a 25 per cent. of hypo.

The advantages of this mode of converting the free silver is, that you can use any strength of silver, so long as you float a sufficient time. Tone with less gold, and no fear of mealiness, or lack of brilliancy. Should you think this worth insertion, you can do so.—I remain, yours, &c., A Cure.

Talk in the Studio.

South London Photographic Society.—The next monthly meeting of this Society will be held at St. Peter's School-room, Walworth Road, on the evening of Thursday next, when a paper will be read by Mr. Valentine Blanchard.

Photographic Exchange Club.—The referees met last Monday evening for the purpose of examining and classifying the specimens forwarded. A large number of prints of very varied character passed through their hands. We shall have something to say on the subject in our next.

M. Joubert's Enamel Photographs.—M. Joubert had the honour of attending at Buckingham Palace a few days ago, for the purpose of exhibiting specimens of his photographic transparencies enamelled on glass, to Her Majesty and the Prince Consort. Her Majesty and His Royal Highness expressed themselves highly pleased with the pictures, several of which they ordered.

Formic Acid in the Developer.—A correspondent writes: "Two days since I tried formic acid in an iron developer, adding 1 ounce of acid to 6 ounces of ordinary developer. The day was very dull, and the view was up a brook, with deep shadows under the bushes along the sides. I gave two wet plates each 1 minute's exposure. In the deepest shadows the ordinary iron developer brought nothing out, whilst that to which formic acid had been added, gave some detail in every part.

Elementary Instruction in Science.—It may be of interest to some of our readers to learn that Mr. Highley, who has been for some time past connected with our contemporary the *British Journal*, is about opening a class-room and laboratory, at his residence in Dean Street, Soho, for elementary instruction in science. His programme includes the following subjects: photography, its principles, practice, and applications; the microscope, its accessories and manipulations; the rudiments of zoology; the principles of mineralogy; and the elements of geology.

Photography and the Drama.—For the first time, to our recollection, photography has been made an important element in working out a dramatic plot. In Mr. Dion Boucicault's new "sensation" drama, the Octoroon, now performing at the Adelphi, a photograph is made the *Deus ex machina* for detecting a murderer. A camera containing an excited Daguerreotype plate being within range of the scene, a portrait of the criminal is secured. How the plate is developed we have not learnt, such accounts of the plot as we have seen being silent on this point. At an early opportunity we must inquire further. Possibly the author is aware of a self-developing process!

Robbery at M. Silvy's.—Francesco Bianchi, Italian, residing at No. 11, Conduit Place, and described on the charge-sheet as a secretary, was charged on Saturday last at the Marylebone Police Court with stealing from No. 38, Porchester Terrace, since the 14th instant, fifteen gross of *cartes de visite*, thirty photograph copies of the "Beauties of England," being portraits of some of our most eminent ladies, twenty other photographs, two miniature cases, and other articles, to the value of £91, the property of Camille Silvy, who deposed that on the 25th he heard that some of his pictures had been offered for sale without his consent or knowledge. Some things were brought to his house, which he identified as belonging to himself, and which he had not missed. He was a photographic artist, and prisoner was employed by him. Vincent Silvani and Angelo Anguissola, Italians, were both called into the box, but their evidence could not be understood, as they spoke English so badly. Pink, 85 D, stated that he received information from the prosecutor that a number of his valuable photographs, which had not yet been published, were being sold in London, and that they must have been stolen. From inquiries he made he saw Bianchi go into No. 156, Bond-street, where he offered several pictures for sale. That (Saturday) morning he again saw him in the Edgware-road, after which he went to Anguissola's residence in Marylebone-lane, where he was followed by the officer, who found a large number of prints there. The officer took possession of these, and in company of the two witnesses went to the prosecutor's house, where they pointed out the prisoner as the party who offered them the photographs for sale. The prisoner then said he was guilty; that he had stolen them because his wife had been writing from abroad for money. He was then taken to the station and charged. Prisoner was remanded for the attendance of an interpreter.

To Correspondents.

*** The Photographic News Almanac will be ready in a few days. It will form a complete epitome of the art, with all improvements, as at present practised.

M. R.—The collodion process is *the* process for a beginner in photography. Commence as suggested with stereoscopic pictures. The two works you name will prove excellent guides. Write to us when you meet with any specific difficulties, and we will try to help you.

C. J.—The glass received. A report upon it in our next.

An Old Subscriber.—We can only suggest such a remedy as you propose, namely, a varnish of india-rubber. Possibly, rubbing with the slightest trace of oil might answer.

T. W. S.—The backgrounds of glass positives are coloured with powder colours, prepared for the purpose, and applied carefully by means of a large camel's hair brush. See Mr. Wall's work on Colouring, recently published at this office, or "Newman's Principles and Practice of Harmonious Colouring" 2. You will find in practice whether your toning bath is any worse. If the gold has become precipitated from some cause, your only plan is to make a fresh bath. 3. The best mode of getting a good print from a negative the lights of which print through too much, is to use a highly albumenized Rive paper, a strong silver bath, and print in the shade, instead of sunlight. 4. Negatives may be vignetted in the camera by using a screen of the right colour, with a serrated aperture of the right size, just in front of the lens. We have described the plan more than once recently in the News.

A Subscriber, Norwich.—The circumstance must be an accident. We will enquire about it, and see to the remedy.

C. C., Belgium.—The Birmingham Exhibition has only just closed, and you will doubtless receive your print. We saw it there, properly hung.

N. Oliver, B.C.S.—Your picture is very good for a beginner. The chief fault is want of sharpness. In a portrait always see that the face is quite sharp, whatever else may be deficient. The present lecturer on photography at King's College is the same Mr. Dawson, recently of Bruce Castle. We quite agree with you as to his entire fitness for his present position.

Annesley Free.—We have repeatedly recently recommended the toning bath with acetate of soda, and given the formula. Use 30 grains of acetate of soda to each grain of chloride of gold, and about 5 oz. of water. You will find a detailed article on printing and toning in the Photographic News Almanac for 1862.

Photographic Amateur.—Cyanide of potassium will remove fresh silver stains from linen. It will be more readily done if a solution of iodine and iodide of potassium be applied first. See detailed instructions on p. 345 of the present volume.

W. J. P.—Photographs cannot be taken by the light of a common gas light. The only available means we know of taking photographic portraits by night is with the aid of Moule's Photogen. The light is not so good or so manageable as day-light; but where night portraits are required, it may be used with a certain amount of success.

James Russell.—We have forwarded the letter to Mr. Fox. The almanac shall be sent when ready. The only person who makes any portion of the solar camera that we know of is Mr. Atkinson, of Liverpool. Any brass worker could make the part you require, if you can furnish him with pattern or instructions. Possibly your own mechanical ingenuity may enable you to contrive a means of getting all the motion you will require. You should endeavour to see one.

S. S.—We do not recommend the No. 1 B lens, to which you refer as preferable to the stereoscopic lens, if it be required for ordinary stereoscopic work only. The reply to which you refer was in relation to a specific case. It would only be preferable where great rapidity was desirable, the advantage being that a larger field in good focus could be produced by its full aperture, than could be by the other. The front lens can be used as a single lens, the focus being about 9 inches. Mr. Sutton is a first-rate operator, and can produce excellent negatives. Of course, we can give no information regarding those of which you speak. Our own time is too fully occupied to permit us to undertake such duties. Regarding the development without the addition of silver, all we can say is, that we have succeeded with every plate we have tried, prepared by different persons; and so have many others. Try it.

G. H. C.—The shade had better not touch the lens tube. Bear in mind it must be a sufficient distance in front of the lens to act as a shade at all. If it be in contact with the lens, it will only serve as a diaphragm, and will not shade off the sky.

F. M S.—The camera should be placed opposite the chest for standing figures. If it be higher, the feet will suffer. If it be lower, you get a view of the face too much under the features, and the effect is not good.

G. G.—The reason why mahogany or other expensive woods are always used for cameras, is simply that most commoner woods would warp and twist, and the utmost truth in the make, and the best standing qualities in the wood are imperative. 2. A tripod stand is not suitable for the operating room; it is liable to be knocked over from its feet spreading so much. A small closet may be used for a dark room; but it is desirable to have as much space as possible in order to do the work conveniently and well. Some means of ventilation are imperative. Water laid on, and a sink, are of the utmost importance.

Excelsior.—You ought to obtain instructions with the Jamin lens for using all its combinations. When used as a portrait lens with the 3rd or central lens in its place, the focus is shortened, and the action made more rapid The ¼-plate lens so arranged, is not suited for card portraits, as it will not cover sufficiently. For such work it must be used without the central lens. There is a method of using the extra lens in conjunction with the front one for landscape purposes. The orthoscopic lens is chiefly used for copying or architecture.

T. W. H.—The law of copyright, as relating to works of fine art, is in a somewhat indefinite state at present, so that it is doubtful how far the law might prevent your copying copyright engravings; but there is no doubt morally about the dishonesty of such a practice.

Robert Sawyer, and several other Correspondents in our next.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to 32, Paternoster-Row.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 171.—*December* 13, 1861.

THE PHOTOGRAPHIC EXCHANGE CLUB.

The classification of prints under the new regulations of the Photographic Exchange Club was completed for the first exchange last week, and we presume by this time the exchanges are in the hands of all the members. Somewhere between three and four hundred prints were forwarded for exchange, varying in size from stereographs to eleven by nine, and varying in quality from first-class to as bad as bad could be. Although the gradations of merit or demerit were perhaps more numerous, it was found sufficient for the purpose of the referees to divide the prints received into five classes. These consisted of first, second, third, and fourth, and, we regret to add, it was necessary to head one column as "rejected."

In forming their judgment the referees were guided not simply by the quality of the photography, but also by the artistic merits of the pictures, the rarity of the subjects, and the amount of effort involved in securing them. A choice or rare subject with third class photography generally secured a place in the second class for exchange; whilst a piece of the most perfect photography, which merely consisted of a series of uninteresting brick buildings, taken out of the operating-room window, apparently to try a plate, or a very perfect view of flat country, without one feature of interest, was always uncompromisingly thrust into the fourth class if it were not rejected altogether.

The question of rejection cost the referees much anxious consideration. They were very unwilling to regard any of the pictures with unnecessarily harsh criticism, and felt great hesitation in discouraging the efforts of even the least experienced. It might have been quite easy also to have exchanged any that were rejected with others as bad, which were also rejected. But it was considered that in doing this, much of the educational value of the exchange system would have been destroyed. The beginner or bungler, as the case might be, might easily take the flattering unction to his soul that there were others at least as bad, nay worse than he, for in such case it is but human nature for each to regard the bad pictures of his neighbours as still worse than his own. It was then finally determined therefore, when anything fell below a certain standard, if it contained either nothing in the subject, or nothing in the treatment to give it any interest, or if from very palpable carelessness or culpable indifference, it was imperfect in manipulation; that in all such cases the picture should be returned to the sender as unsuitable for exchange. We regret to say there were some very glaring cases of unfairness, which compelled the referees to use the rejected class without scruple. Some had, apparently, made a collection of their waste prints, such as were under-printed, over-printed, soiled, stained, or otherwise imperfectly manipulated. This is altogether too bad, and should only be met by committing the prints to the flames, without the trouble of return. Some in the rejected class, were, however, the failures simply arising from inexperience, the faults arising chiefly from under-exposure. Those members who have sent their best results must not be disappointed, if they find them returned as unsuitable for exchange; but take courage and continue sending until they attain sufficient excellence for acceptance. Whilst the referees cannot undertake, as in some instances they were requested, to enter critical correspondence with members, as that would involve a responsibility altogether too great, where the services are altogether honorary, they will have pleasure in giving careful consideration to all prints, however imperfect, which indicate that the tyro is doing his best, and will gladly recognize, by acceptance and exchange, the first decided traces of improvement.

There is another ground of complaint against some members, and that is inattention to, or disregard of, the rules laid down. Some members do not state the particulars required, especially as regards the right and left half of stereoscopic prints. Some send a miscellaneous assortment of mounted prints, apparently the weeding out of some collection. This disregard of rules was not made a ground of rejection; but if it be continued, we fear, will in future disqualify the prints for exchange.

We have referred to the faults which have characterized some of the prints first, because it is important that some effort should be made to avoid them. Each member should feel himself bound in honour to send the very best prints he can produce from his best negatives, and also to comply honestly with all the conditions laid down for his guidance. Neglect of any of the conditions of membership imposes additional labour upon those gentlemen who gratuitously undertake the management of the club, and if it be passed over by them is to a certain extent an injury to other members. We have dwelt upon the evils occurring in the first contribution, in the hope and conviction that they will not occur again. *Verbum sap.*

We are glad to be able to record the fact, that amongst the contributions were many very excellent photographs, both large and small, and these in sufficient numbers to justify a hope that the Exchange Club, under its new organization, will prove a source at once of profit and pleasure to the majority of its members.

THE "PHOTOTYPE" CARBON PROCESS.

Most photographers are aware that the carbon process, invented by M. Joubert, and styled by him the phototype process, is at once the most rapid and the most permanent method of photographic printing yet discovered, and the most nearly allied to the ordinary processes of letter-press or copper-plate printing. We have from time to time received enquiries as to the ultimate intention of the inventor regarding the process, whether it was to be given to the public, or patented, or to remain a secret known only to himself. We are now authorised to announce that as his own time is so much engaged in the prosecution of the enamel process, M. Joubert is prepared to treat for the sale of his carbon process, either to the public or an individual on equitable terms. The process has cost M. Joubert a certain amount of time and money, which he is naturally desirous of being reimbursed, and as he is unable from other engagements to work the phototype process commercially himself, he is unwilling to allow it to remain a dead letter to the public any longer. We shall be glad to see some enterprizing photographer, who possesses the necessary capital, work the process successfully. It unquestionably is the best solution of the possibility of carbon printing which has yet been discovered.

BURNT-IN PHOTOGRAPHY.

BY MICHAEL HANNAFORD.

M. Joubert's recent private exhibition of photographs burnt-in on glass, makes it manifest that this branch of art is capable of many useful applications in ornamentation; and as among our readers we number many given to experimentalizing, we would recommend such as have the appliances to turn their attention in that direction.

The process patented by M. Joubert has already been detailed in these pages, but it may not be out of place to give a short *resumé* of it. A piece of glass properly cleaned is coated with the following solution, filtered before use :—

Saturated solution of bichromate of ammonia	5 parts
Honey	3 „
Albumen	3 „
Water	20 to 30 „

A *positive* by transmitted light, on glass or paper, placed on the sensitive plate when dry, will give, after a short exposure to light, a faintly indicated picture, in a negative condition. To bring it out, an enamel colour, in a very finely divided state, is gently rubbed on with a soft brush until the whole composition, or subject, appears in a positive form. It is then fixed by pouring over the whole surface a solution of alcohol containing a small quantity of acid, either acetic or nitric. A gentle immersion, horizontally, in a large pan of water will, in a short time, dissolve out the chromic solution, leaving only the enamel. When dry it is ready to be placed in the kiln for fixing.

The ultimate colour of the burnt-in picture depends entirely on the nature of the "enamel colour" we employ. Most of our readers are aware that in the process of "fixing" the colour of the metallic oxide undergoes in nearly every instance a very considerable change. Thus if, for instance, we place an ordinary negative in the kiln, the black deposit of silver will be converted into light yellow. If our negative be toned with gold the tint will be orange, or red orange, accordingly as the amount of gold is greater or less, this metal giving ruby tint under the influence of heat.

On looking more closely at our burnt-in picture, we shall find that only a portion of the deposit is fixed *in* the glass, the remainder forming a deposit which may be scraped off. If, however, we had added a "flux" to the enamel colour, the whole of the reduced silver would have been retained permanently.

In order that the experimenter may proceed with some degree of system, he will find that a knowledge of the ordinary process of enamelling will be of considerable service. We therefore give a short account of that process, together with a list of the different metallic oxides to be used in obtaining the various tones.

The Process of Enamelling.

A bright metallic surface (gold or copper is best), is coated with a thin stratum of "flux" ("*frit*" or "*paste*"), coloured with metallic oxides, and fused under the blowpipe, or in a small furnace.

The preparation of the film varies, the quality being dependent upon the duration and degree of heat employed. A few of the formulæ are here given.

1. Powdered flint glass 12 parts, powdered flints 4 parts, calcined borax 3 parts, red lead 16 parts; mix in a Hessian crucible for 12 hours, then pour out into water, and reduce to powder in a mortar.

2. Lead and tin equal parts. Calcine in an iron pot at a dull cherry-red heat, and scrape off the oxide as it forms, being careful to obtain it free from undecomposed metal; then reduce it to fine powder by grinding and elutriation. This is termed "calcine." Take of it, and of ground flints, each one part, pure carbonate of potash 2 parts, and partially fuse in a crucible, by which it undergoes semi-vitrification.

3. Powdered flints 13 parts; nitre and white arsenic of each 1 part. Proceed as before.

4. Flint glass, 3 oz.; red lead 1 oz. As before.

By increasing the quantity of *sand*, *glass*, or *flux*, the enamel is rendered more fusible, and the opacity, or whiteness, is increased by adding oxide of tin. Borax is apt to cause efflorescence and loss of colour.

Different colours are communicated by the addition of metallic oxides to flux prepared by one or other of the above methods. Thus, oxide of cobalt gives blue; oxide of iron, brown; black oxide of copper, green; sub-oxide of copper, ruby red; oxide of gold, purple; oxide of silver, yellow; oxide of manganese, amethyst; oxide of tin, opaque white, &c.

Placing the colours in alphabetical order may, perhaps, be more useful for after reference.

Black.—(1) *Calcined iron* (protoxide) 12 parts; *oxide of cobalt*, 1 part. (2) *Peroxide of manganese*, 3 parts; *Zaffre* (crude oxide of cobalt) 1 part.

These are best used with white flux.

(3) *Pure clay*, 3 parts; *protoxide of iron*, 1 part. A fine black.

Blue.—*Oxide af cobalt.*

Brown.—(1) *Manganese.* (2) *Calcined iron* with *antimony.* Oxide of cobalt may be added to alter the tone.

Green.—*Black oxide of copper.* (2) The same, with the addition of a very small quantity of *red oxide of iron.* The colour is less decisive. (3) *Oxide of chromium* enough to colour. The tone is superb, but liable to turn to the dead leaf tinge in inexperienced hands. Transparent flux should be used, (4) *Black oxide of copper* 15 to 20 parts, *oxide of chromium* 1 part, with transparent flux. This last colour is nearest to emerald. (5) *Blue* and *yellow enamel* in different proportions.

Olive.—*Blue enamel*, 2 parts; *black* and *yellow* do., of each 1 part.

Orange.— *Red sulphate of iron* and *oxide of antimony*, of each 1 part. Melt with flux containing a large proportion of read lead.

Purple.—*Oxide of gold*, *purple precipitate of cassius*, or *peroxide of manganese.*

Red.—(1) *Red oxide*, or *protoxide of copper.* Should the colour tend towards green or brown, from partial pertoxidisation, the red colour may be restored by the addition of any carbonaceous matter, as tallow, or charcoal. (2) The *salts of gold* produce shades of red, inclining to crimson, of the most exquisite hue. (3) Red sulphate of iron, with flux containing a large proportion of red lead.

Rose.—*Purple enamel*, with *oxide of silver*, according to the tone desired.

Violet.— *Peroxide of manganese*, with alkaline flux. Contact with carbonaceous substances should be carefully avoided.

White.—*Oxide of tin.*

Yellow.—(1) *Oxide of silver.* (2) *Oxide of lead*, with a little *red oxide of iron* fused with flux. (3) *Lead*, *tin ashes*, *litharge*, *antimony*, and *sand*, of each 1 part; *nitre*, 4 parts; mix, fuse, and powder; and add the product to flux. (4) *White oxide of antimony*, *alum*, *sal ammoniac*, and *pure carbonate of lead*, of each 1 part (all in powder); mix, and expose to heat sufficiently high to decompose the sal ammoniac. Used as last. Very bright. (5) *Oxide of uranium*,

(To be continued.)

Scientific Gossip.

Mr. Casella, the well known meteorological instrument maker, has lately introduced to the scientific portion of the public a new minimum mercurial thermometer. Although such instruments are, strictly speaking, meteorological rather than photographic, yet they are so frequently used by scientific men as well as by the better informed portion of the general public, that we think a short account of this one will prove of interest to our readers, more especially as it accomplishes what no other thermometer has yet been able to effect; namely, give a correct and invariable record of the lowest temperature which has occurred during any given time. Scientific men have long been striving to devise some such instrument whereby the extreme of cold could be registered with the same fluid (mercury) which is used to record maximum temperatures. The late Mr. Welsh, the talented director of the Kew Observatory, repeatedly turned his attention to this subject, and at length gave it as his opinion that the construction of a mercurial minimum thermometer was a physical impossibility. Physicists were therefore forced to rely upon the indications given by spirits of wine, which is the least objectionable of the other available fluids. This, however, possesses many disadvantages. Owing to its being a bad conductor of heat it is sluggish in its movements; moreover it wets the capillary tube, and that in so uncertain a manner as to preclude the possibility of proper compensation in graduating; it is likewise liable to evaporate and condense in minute, colourless, almost invisible bedewments in the vacuous portion of the stem; and in tropical countries these objectionable features are intensified. Furthermore, a mercurial thermometer can obviously be made more delicate than a spirit one, and mercury can easily be obtained pure and constant in properties, which is not easily attainable in the case of alcohol. It will thus be seen that in bringing out a mercurial minimum thermometer, Mr. Casella has conferred an important boon upon scientific men. The principle upon which its action is based is very ingenious. The maker has employed the two forces, the cohesive power of mercury to itself and the adhesive power of the metal to glass, in a most ingenious manner, so that they can act in opposite directions. A small pear-shaped chamber, with a capillary orifice, is connected by a bent tube to the bulb end of an ordinary mercurial thermometer. The end of the chamber adjoining the tube is cut off abruptly, so that its flat end, with the fine capillary hole in the centre, forms one end of the tube. The instrument is filled with mercury in such a way that its lower portion is full of metal, except the little chamber, and the stem is then graduated in the usual way. In order to set the instrument, it is suspended horizontally, and the bulb end gently raised, and if necessary, tapped until the mercury begins to flow out of the chamber. The instrument is then lowered on to a support at a gentle incline, and kept so; the column of mercury continuing to obey the law of gravitation, and flow up the thermometer tube until the little supplementary chamber is empty. The force of adhesion between the mercury and the flat end of the chamber which nearly closes the bent tube, now exerts its influence, and holds the mercury close to the diaphragm, preventing its further rise in the stem. The instrument is then allowed to remain undisturbed, the column of mercury indicating the temperature of the surrounding air. It is now influenced by an alteration of temperature in the following manner:—If the temperature of the air becomes colder, the mercury will contract, and in contracting it will exert itself in opposition both to the adhesion between the mercury and the glass of the capillary bore in the long stem on the one part, and the adhesion between the mercury and the flat glass diaphragm of the supplementary chamber. The former adhesion being the weakest, the mercury will only contract out of the graduated bore of the tube, and the temperature will be seen to "fall." But suppose, now, that a rise of temperature takes place; the mercury will expand, and in this case also will have two directions in which it can move. It may either "rise" in the graduated stem of the instrument, or it may expand through the diaphragm into the supplementary chamber. In the former case, however, it will have to overcome the adhesion which the capillary bore of the tube exerts upon the fluid, whilst there is scarcely any resistance to oppose its expansion into the chamber. A rise of temperature, therefore, does not affect in the slightest degree the position of the end of the recording column in the graduated tube, but merely causes a certain quantity of mercury to flow into the chamber. Suppose, now, that the temperature sinks a little, the first action is to draw some of the mercury out of the additional chamber; as the temperature sinks, the mercury is drawn out until it reaches the diaphragm. The temperature at this point is exactly the same that the column in the longer tube points to on the graduated scale, and now the mercury having reached the diaphragm of the pear-shaped chamber, all movement at that end of the instrument ceases, and the further contraction of the metal takes place in the graduated stem. It is thus seen that whatever be the number or amplitude of rises and falls of temperature during a given time, the end of the column of metal in the graduated stem always points to the *lowest* degree of temperature to which it has been subjected. We have been thus explicit in explaining the construction of the instrument, inasmuch as there is a great deal of misapprehension in respect to its *modus operandi*. It is not easy to understand without a careful examination of the instrument itself, and hence really scientific men who ought to know better, have fallen into grave errors respecting its working, and have, moreover, given their erroneous impressions to the public in print. The most common fault of which this thermometer is accused, is that it will only register the minimum temperature provided there has been a constant fall from the time the instrument is set to the time of greatest cold. An attentive perusal of our above description of its working will show this opinion to be founded upon a totally incorrect idea of its mode of action.

The proper colour of pure water has long been an interesting subject for speculation and experiment. We have already given in these columns an account of the fine experiment of Dr. Tyndall, in which he threw a beam of electric light, in the form of a circular disc, on to a white screen, the upper portion being allowed to pass simply through air, whilst the lower rays were sent through fifteen feet of water; thus clearly showing that the water was of a blue colour. Some further researches have now been made by Dr. Wittstein, in which, whilst corroborating Tyndall's results, he throws light upon the variations from the normal blue colour which is frequently noticed in natural waters. From analyses performed by himself and others, of the water of several rivers in Bavaria, he arrives at the following conclusions:—1. Pure water is not colourless, but blue. 2. Mineral substances dissolved in natural waters do not alter their colour. 3. The various colours of natural waters are due to dissolved organic matter. 4. This organic matter is retained in solution by the aid of an alkali; it is in mass of a deep brownish black colour, in dilute solution of a yellowish brown colour; and belongs to the class of bodies known by the name of humus, or humic acid. 5. The quantity of the organic matter in solution depends solely upon the quantity of the alkali. 6. The less organic matter is dissolved in the water, the less does its colour vary from blue; with an increase of the organic substance, the colour gradually passes into green, yellow, and brown, the blue being gradually obscured. 7. Every natural water meets with a considerable portion of one agent changing the colour, namely, humic acid; whilst the other agent, the alkali, is distributed in very variable degrees: the colour of waters poor in free alkali, therefore, approaches blue most closely; an increase of the alkali causes an increase of humic acid, and, consequently, a change of colour into green, yellow, and brown. 8. It follows, therefore, that the nature of the rocks over which the water flows furnishes the principal condition for the colour of water. 9. Periodical changes of the colour of the same water are not caused by a different amount of organic matter, but are dependent upon atmospheric conditions, such as cloudy sky, fog, &c. 10. As a general rule waters are softer the more they approach the brown, and the harder the nearer they come to the blue colour. The cause is not the amount of organic matter, but the amount of alkali contained in solution, on the latter of which, however, depends the proportion of the former. These results are more important than they would appear to be at first sight. As a satisfactory solution of a problem in physical chemistry they deserve considerable attention, and they more especially merit notice from our readers on account of the light which they are calculated to throw upon several photographic phenomena. The colours of lakes, rivers, and other masses of water are known to vary considerably both to the eye and also in their photographic action; these results of Wittstein satisfactorily explain the reasons of this: whilst, if subaqueous photography should ever rise from the position of a scientific *tour de force* to that of an every day performance, the correct understanding of the causes of the variation in colour of the surrounding medium cannot fail to be of the highest importance.

Two samples of glass have been forwarded to us, marked respectively C 1 and C 2. C 1 is a flashed glass, and in C 2 the colour is in the body of the glass. They are of a brown colour, and in the spectroscope are seen to allow large quantities of chemically acting rays to pass through. They are therefore comparatively worthless for photographic purposes.

MY IMPRESSIONS OF PHOTOGRAPHY IN PARIS; AUTUMN, 1861.*

BY C. JABEZ HUGHES.

What a world of change is experienced in some ten or twelve hours by the transit from the hard, matter of-fact, overcrowded, dingy London streets, to the gay, free-and-easy, jaunty, pleasure-inviting, boulevards of Paris. With a sort of steam-engine hop skip-and-a-jump you leave the wharves of the Thames and light on the banks of the Seine—and are in a new world.

Here is Paris; the same clear blue sky, dry air, and smokeless atmosphere that it had two and ten years ago. Alterations may be made, new Louvres built, old *quartiers* demolished, mammoth boulevards formed, fresh barracks, more soldiers, but Paris is still Paris, *toujours Paris*. There is the same happy-go-lucky, holiday look about the people, as if they never were thoroughly in earnest, making amusement, not labour, the main object of life. This is not, perhaps, the place to indulge in one's thoughts of the difference between the English and the Frenchman; but one's attention cannot avoid being forcibly arrested. The one is all work and little play, and so he is a dull boy; the other all play and little work, hence he is a gay one. The former is, comparatively, a dull beast of burden, the latter a frivolous butterfly, and the conclusion cannot be avoided, that both extremes are bad, and that if the commercial treaty could produce not only a modification of tariff but of character too, an immense advantage would be gained.

Being deeply interested in English photography, and with some knowledge of its present condition, I could not avoid making some comparisons. My impressions, such as they are, I wish to be received as hasty observations snatched during the prosecution of other business, and therefore open to the remark of being superficial and perhaps erroneous. In walking about the streets of Paris, and observing the specimen cases so plentifully displayed at the corners, I saw a great change had been made during the last two or three years. Formerly, the cases were filled with "touched up" pictures, having "put in" backgrounds. There were also abundance of coloured ones in oil and water-colours, with all sorts of interior and exterior background monstrosities. All these have been ruthlessly swept away by the Cartes de Visite mania. Like Aaron's rod, it seems to have absorbed everything. Here and there a few whole-plate or larger pictures are seen, but they are evidently some of the old staff, retained in the establishment for former services rendered, and to show to customers not bitten by the new mania, that the art of taking pictures larger than the quarter-plate is not forgotten. But high and low, rich and poor, in establishments good, bad, and indifferent, the absorbing idea, to the exclusion of all else, is the *Carte*. As at home, all the stationers and fancy dealers have their shop windows filled with portraits of every local, and general celebrity. The number of impressions of these portraits that are printed at some of the principal establishments is stupendous, and I should be sorry to trust myself to name the figures, for fear of being charged with romancing.

I was much surprised at the utter absence of glass positives everywhere. I had previously noticed that the French never took kindly to them. It is true they rarely produced good ones, yet a few years ago I saw at an establishment in Rue Vivienne some as fine as I have ever seen, Mr. Lee's, of Liverpool, always excepted. The French had a passion for stripping these positive pictures off the glass on to black cloth or leather. Their tone—never very good—was thus made worse, and I am not surprised that they were abandoned. Following in the wake of poor Daguerreotype, they are only seen on the extremities of the faubourgs, among the poor blouses, and seem half ashamed to be discovered there. My attention was once arrested in an out-of-the-way suburb by a shabby looking case of specimens, nearly all of which were glass positives. They were very dark, dirty, and stainy. The printed notice in the case, however, was curious, for it informed the public in general, and his neighbours in particular, that the proprietor followed the joint occupations of blacksmith and photographer. At home I had seen, with displeasure, the unhappy union of photography with ice and roast-chesnut shops, with barbers and cigar shops, with Greenwich and Gravesend tea and shrimp-rooms, but this was a new combination of the *utile* and the *dulce*. I looked in at the man's establishment, or yard rather, and, under the plea of inquiring prices, had the opportunity of taking observations. On one side of the yard was a smithy, with some bars of iron in the fire and a boy blowing the big bellows. On the other side was a kind of shed, with a calico covering over one end. This was the "glass room." A piece boxed off at one end formed the dark room. A franc was the charge to be operated on, *passe-partout* extra; colouring was a luxury he did not humour his customers with. A female who preceded me was prepared to submit. The staff to manage both establishments consisted of the artist and the boy already named. With a bow worthy of Count Persigny the artist begged the female to be seated, and, taking a glass, gave it two or three rubs with his leathern apron, proceeded to pour on the collodion. Thinking I had discovered a cause of his dirty, stained plates, and not wishing to be witness of more indignities on my favourite art, I prepared to leave, when two more customers entered—a part of heavy cart horses—who were ordered to be shod *toute suite*. Business was evidently brisk, so lifting my hat, and with a *bon jour*, I departed to the more congenial *atelier* of my friend Bingham.

During former visits to Paris the impression was that photography was destined to pass into the hands of the artists, for few prints were seen except touched up, or coloured, so that the poor photograph was lost. This illusion is happily dispelled, the age of reason has returned; pure and unalloyed prints are heartily believed in, and fully appreciated.

The practice of vignetting I did not find so much adopted as I should have expected among our taste-loving French brethren. The engrossing anxieties about the *cartes* are, however, sufficient to prevent the practice of that or any other kindred novelty that depends on delicacy of manipulation.

I found a grievous deficiency of landscape photography as compared with ourselves. I looked in vain for quiet beautiful landscapes, charming pastoral scenes, and those sweet pictures of nature that we are so familiar with at home. France evidently has no Bedfords, Heaths, Mudds, or Wilsons. I know not to which country Maxwell Lyte yields fealty, but supposing him French, then an Englishman is their best in this role, but clever, truly clever as he be, he is by no means up to the standard of the names I have mentioned, especially as evidenced in their recent works. The French in their nature seem more demonstrative and noisy than ourselves. When they want landscape they rush to the Pyrenees, choosing black gorges, or ice-clad mountains, with glen torrents, and sterile peaks, instead of selecting those scenes of quiet beauty with which the mind is daily familiar, and upon which it always longs to gaze.

* These autumn impressions have been deferred until winter from press of matter.

MM. Bisson *Frères* need not so frequently rush to Switzerland when the banks of the Seine are so closely at home, and while the Bois de Boulogne contains some of the most charming examples of landscape gardening. It certainly is from no inability to do good work, that this deficiency of good landscapes arises, as was proved years since by those almost poetic scenes that Silvy produced when an amateur. Witness also the many charming views by Count Aguado, to whom the beauties of the real "Champs Elysée," the Bois de Boulogne, are by no means unknown. I am not insensible to the great merit of some of the pictures of Baldus who has shewn full capacity to produce lovely landscapes, and of great size too. M. Jeaurenand too has recently shewn some lovely pictures from Taupenot negatives that might almost be taken for Mr. Mudd's, especially as his method of printing the skies is so similar and equally effective.

Stereoscopy seemed to be on the decline. True many of the shop windows are crowded with slides, but they looked like old stock, and a great number, indeed most of the groups, are English ones. I was sorry to see Her Majesty, and the members of the Royal Family figure so indifferently in the shop windows. Nearly all the prints I saw were poor copies, and not original prints at all. That vile habit of piracy does not appear to exist in Paris, and they must have been imported.

Among the professional photographers, I was pleased to observe less of that keen competition and desire to undersell each other. There is very little of the cheap and common portraits. I did see a few, very few, in out of the way places, like our photo-blacksmith, that took franc pictures, but three francs seemed to be the low price among the hardworking neighbourhoods. It struck me that there were not nearly so many photographers in the common neighbourhoods, and certainly the class of work is much better than with the same class among ourselves. It was a great blessing to find an utter absence of "touters." You may stand and look at a case of specimens at a man's door till you are tired, without being annoyed, insulted, or assaulted.

I spent a good few hours in the Photographic Exhibition, studying the vast collection of grand pictures. I have seen nearly all our exhibitions, but the present Paris one far exceeds any one we have ever yet had in this country.

My remarks respecting it I had better reserve for another paper.

ON WASHING POSITIVE PROOFS.

BY GEORGE SHADBOLT.*

There are, perhaps, few photographic manipulatory operations that are looked upon as so excessively tedious as that of the final washing of the otherwise finished proofs. In fact, every kind of "dodge" has been resorted to in order to lessen its irksomeness, and, if the truth must be told, to shirk the trouble involved in a thorough removal of the last traces of the fixing agent and what it holds in solution, and which, from its great solubility in water, requires an enormous amount of that fluid to be applied with no little judgment in order to effect the object in view. With most operators, the grand panacea for defective washing appears to be considered as existing in an unlimited supply of *running water;* but, apart from the injurious action which a very long continued immersion in water entails upon the photographic proof, by partial removal of the size from the paper, and other deleterious influences, I am altogether incredulous about the removal of the double hyposulphite of soda and silver by any length of immersion merely, even in a running stream. I have frequently been called upon to give advice to those engaged professionally in printing operations, relative to this very question, and have indicated a course of proceeding which, in no single case, have I found to fail, nor has any one who has tried it complained of on account of inefficiency; but, I am bound to admit, that several have abandoned it because of the alleged extra trouble involved.

The plan to which I allude is the employment of many changes of water at moderately short intervals of time, say every ten minutes, but being careful between each change of water to hang up each print separately to drip for several minutes. By this operation the print becomes divested of by far the largest portion of the adhering fluid contaminated with the double salt of soda and silver, and is in the best condition, on its re-immersion into fresh water, to allow the small remainder of the deteriorated fixing solution to become still further diluted.

I am ready to concede that this plan entails some extra trouble; but the question is, whether the advantage gained be not well worth the trouble? And I contend also that, in practice, the extra labour is not nearly so much as is generally supposed, while it must not be forgotten that the kind of labour requisite is not of any costly value, but little skill being demanded for its performance, and in addition, it by no means follows that we may not by some ingenuity be able to reduce the amount of the extra labour, as we now please to regard it.

For suspending photographic paper while drying, after any of the operations to which it has been submitted, I have for many years past made use of the wooden American clips, commonly used for clothes pegs, and which are procurable at the rate of about one shilling per dozen. By thrusting a common pin through one side of the clip, near the open end, and turning it into a hook by means of a pair of pliers, the clip itself can be readily suspended across a cord, wire, or slip of wood, and the paper proofs are not torn, but held between the jaws of the clip, just as they would be by the finger and thumb. I propose then to apply these American clips to economise our labour, as follows, viz.:—after the first soaking of the proofs in water, when fresh from the fixing bath, I would hang each one up by aid of *two* of the clips, that is, one at each of the upper corners of each sheet, in such a manner that one angle of the sheet of paper should hang somewhat lower than the other, in order to assist the dripping of the fluid, which might be farther encouraged occasionally by the touch of a glass rod for a moment. A washing cistern, of a depth sufficient to receive the proofs in a perpendicular position, should be placed under a tap, and have a hole in the bottom near one of its corners, to let the water run out, and which can be stopped by a plug, or any other convenient method. Several metal or wooden rods, long enough to reach quite across the cistern, should be provided, and admit of being supported each upon a couple of hooks, at some little distance from a wall. As each proof is removed from the first washing water, the two clips are to be attached, as already described, and these can be hung by aid of their pin-hooks on to the rods. Each rod may take six or eight proofs. When all are hung up, the water in the cistern may be allowed to escape, and the cistern re-filled, during which time the proofs will be losing the water adhering to them; then the rod on which the first prints were hung may be taken up bodily with its suspended prints, and the latter lowered gently into the fresh water, the ends of the rods resting on the sides of the cistern.

I am aware that the prints will have a tendency to rise towards the surface, but by very little care they may all be made to sway in one direction, and as soon as one set is properly in, a second rod may be inserted next to the first, and so on until the cistern will hold no more. By the time the last has been set in, the first will have probably been in about ten minutes, and may be taken out again and hung up as before, and the whole operation repeated as many times as may be found needful—probably about a dozen times will be quite sufficient—so that in a little more than a couple of hours, a considerable number of proofs may be more thoroughly washed from the remains of the hyposulphites, than are done by the present method in from six to twelve times as long a space of time. It is much to be

* Read at a Meeting of The Photographic Society, December 3rd, 1861.

regretted that we do not possess any reliable test for very minute quantities of the hyposulphites remaining in the prints—personally, I prefer that of the taste to any other—nitrate of silver, and nitrate of mercury, have both been used, but I find that long after I have been unable to detect any remains of the hyposulphites by them, after hanging up the print until surface dry, the small remaining drop of liquid at the corner is appreciably sweet to the taste.

I am aware that a method of warming a suspected print is employed by Mr. George Dawson, the recently appointed lecturer on photography at this college, when a slight scent of sulphur is detected by him, but I find my sense of taste more acute than that of smell.

I have frequently sought to devise some means by which the noxious hyposulphites might be converted into some innocuous substance capable of ready removal; but, unfortunataly, this plan involves decomposition, the direst evil we have to dread, as it appears to be to the decomposition of the hyposulphite of silver that most of our spoilt prints are due.

I fear that I may run some risk of being charged with taking up your time with too trivial a matter for consideration, but I have done so upon the grounds that small annoyances by constant repetition become great evils, and I have found from experience that at this, as well as at some other societies, although the paper read may, *per se*, be of little value, it not unfrequently originates a discussion, from which much that is useful and instructive arises. I will therefore conclude, with a hope that my very slight suggestion may do so upon the present occasion.

A PROLOGUE FOR THE SEASON.

BY VALENTINE BLANCHARD.*

In the good old times when good Queen Anne was on the throne, no play was considered perfect without its prologue and epilogue. In these modern days, however, they are quite out of fashion, and are stowed away upon the dusty shelves of the bygones. Is it that we have no Popes, no Addisons, nor Goldsmiths to write them, or is it that they might raise expectation too high, and call attention to the literary shortcomings of the modern drama? We will not pursue this speculation further, but we think we may, with propriety, borrow the word for our remarks. At every annual meeting we have, what we will call, the epilogue in the secretary's report, but thus far we have had no prologue.

Now we do feel strongly impressed with the conviction that all societies like ours might, with advantage, devote the first evening of the season to an introductory address, briefly reviewing the past, but more especially chalking out clearly, in bold outline, the course for the future. In the discussion which would follow this address, many new suggestions would be given forth, some of which might be adopted with great advantage, and would tend to throw new life and vigour into the meetings of the society, giving at the same time increased pleasure to the members.

We cannot help feeling that hitherto the course of our photographic societies has rolled on too smoothly in the well-worn tracks of routine, and the time has come when we may with advantage seek out new paths, even though the roads may not be quite so smooth. At least there will be the charm of variety, which will banish the listlessness and shake off the drowsiness into which some of us have fallen.

If we glance at the early history of the parent society, we shall find it had its origin in the efforts of a few photographic enthusiasts to remove the patent restrictions which held our beautiful art in the chains of bondage. All honour to them for their successful labours. The names of some of them have become "as familar in our mouths as Household Words," and others of them alas are gone from us; but they too have left

"Footprints on the sands of time."

Years have rolled smoothly on since the London Photographic Society first commenced its labours, and it has gradually grown into a goodly body, but it has scarcely, to our thinking, used well the means at its disposal. The tendencies of the age are ever onward, and woe to those who lag behind. We would like to see the parent society the *avant courière* of photography, and not a Lord Mayor's coach, broken down by its own stateliness.

If we look at the origin of our small, but not "very small." society, we shall find that our worthy secretary was paternal and maternal progenitor, nay, even godfather and godmother as well. We all owe him much for his untiring labours; but we do think some of us mistake the way to show our gratitude. In all seasons we find him at his post. Nothing keeps him from his duties, not even the terrible wind, which Dickens tells us always roars with tenfold vigour at Walworth. That he is right we all know, for on one or two occasions last season, the speeches could scarce be heard, so lusty was the voice of Boreas in spite of his hoarseness. No, Wall had plenty of the cement of the Roman in his frame, and was always to be found the right wall in the right place. We are sure then nothing would repay him for all the sacrifices of time he has made for us, so completely as a regular attendance on the part of all the members at the meetings of the Society. We think all of us can look back with pleasure to the past season. The attendance, however, was not uniform. Some meetings brought but a scanty array of members; now we do hold it an imperative duty on the part of those who join a society like ours, where some of the body put themselves to no small amount of trouble to prepare papers for the amusement and instruction of the members, we do hold it a duty we repeat, resting on each of us individually, to repay the reader for his trouble by being present. Surely this is not much to give for his labour. We have felt so strongly this to be a duty, that during all the time we have belonged to the society, we have been absent but twice, and then we were a hundred miles away.

We all know how easy it is to frame excuses for our absence. We are only too ready to say, "I do not feel much interest in the subject for to-night's meeting;" or, "Well really I should have thought that subject worn out by this time, I shall hear nothing new to-night, so will e'en stay at home;" or we look at the state of the weather, and find that the wind is in the east, and blows with something more than the breath of a zephyr through the balustrades of the bridges, and, with a shuddering twitch of the shoulders at the picture conjured up, and a vigorous poke at the fire to drive off the sensation, we readily enough determine to remain at home, and stifle any qualms of conscience by a promise made to ourselves to read carefully the report of the meeting. If we were, however, to place ourselves in the shoes of the disappointed essayist when he sees but one pleasant wall, and four blank ones to greet him, we should let nothing but illness keep us away.

But whilst we cannot help condemning strongly the indifference displayed by some of the members of our society, and we fear the fault is but too common in other societies besides our own, we believe a cause may be found without much difficulty. We can conceive nothing more pleasant or enjoyable than a photographic gossipping club, where every one can come within the magic circle of sociality, and cast in his scrap of information for the general benefit, without a feeling of apprehension and fear of that most dreaded individual the reporter, which we are sure takes possession of the boldest of us. We can speak from experience, for we never get up to make a remark without feeling a palpable fog—a London one in its completeness—stealing gradually over our mental faculties, and the subject, which stood before us clear as noon-day, has assumed in consequence such a strange

* Read at the Meeting of the South London Photographic Society, on Thursday evening, December 12th.

and distorted appearance, that we ourselves can scarcely make out the outline, and as for colour or details, alas! they are entirely lost to us. To resume, then, in such a friendly circle as we describe, each one speaks with freedom, and, in the comparison of notes, all are in turn gainers; for we do not believe that photographers are, as a rule, miserly over their knowledge. We have, it is true, occasionally met with a man who carries a book filled with precious secrets, each one of which is worth its weight in chloride of gold, but he has invariably shown himself a veritable "mar-all," whose boasted photographic gems are but spoiled paper and wasted chemicals. We fear this pleasant gossipping club would scarcely prove practicable where the number of members is large, but we do think, however, a little of its geniality could be introduced into our meetings to thaw a little of the frost sometimes felt, and which we fear chills some of our members.

Let it not be understood that we desire to depreciate the importance of meetings like the present; such is not our object; but we do think it possible to introduce some new features, which may enhance rather than lessen their value.

We would like the experimental committee to be a committee of the entire Society, for we feel assured that the members generally would be benefited by the change. During the past season we heard of the labours of that body but twice. If our memory serves us rightly, only two reports were laid before the meeting, one of which was passed as read; that is to say, the members were referred to the journals, if they were desirous of learning the contents of that report. We would have a subject announced for investigation. Let it be some new process to test, or some old photographic paradox to clear up. No matter what the subject, let there be sufficient time allowed for experiment, and then, on the evening appointed for discussion, let each member come prepared with the results of his researches. We might then reasonably anticipate a very animated and pleasant evening, the more so if the subject chosen could be illustrated by comparative results. If it were possible to make the experiments in the presence of the members, it would tend in no small degree to clear up many of the conflicting statements now existing on many photographic subjects. This, at present, in most cases, would be impracticable. If, however, members would find time for experiment, and set themselves to work, faithfully recording their failures, at the same time carefully preserving their results for comparison at the meeting, we could not fail to be gainers, and the subject would, in consequence, awaken the interest of all the members.

Our great desire, however, is to see classes for the study of chemistry and optics organised in connection with the society. We do not think this proposition will be regarded as impracticable, for we have already amongst us men whose attainments, in both chemistry and optics, stand deservedly high; for not only are they well versed in the theory, but have daily to combine it with the practical parts of these sciences. We feel assured that these gentlemen would gladly aid us in our endeavours to make this society more thoroughly educational than it has hitherto been. The future of all Photographic Societies should lie in this direction, for how invaluable to all engaged in the practice of photography would be knowledge of chemistry and optics. Now the professional photographer has but few opportunities of acquiring a knowledge of these sciences, beyond the fragmentary information which must present itself to him in the course of his labours, for chemistry is one of those sciences that it is almost impossible for one to pick up by himself. It is always more easily taught in class. Besides, the expense is an important consideration. When, however, it is shared by the many, the difficulties are at once removed.

We feel assured no one here will underrate the importance of a knowledge of chemistry to all photographers. We know there are some who say sneeringly—Well, I don't care about so much theory, give me the practical part. They seem, however, to lose sight of the fact, that they are very much in the condition of the child on the lap of the mother; they are helpless until the food is put into their mouths. Such men eagerly swallow all that comes in their way, and then snarl by way of payment. No; we all owe much to the chemist for his patient, plodding labours, and for his microscopical powers of observation; and we long for the time when we can follow him in his labours, and fully understand his power of producing those combinations which, like the score of a grand symphony, can be written in a language wholly unintelligible, presenting to the eye of the uninitiated a confused mass of figures and letters, strange hieroglyphical characters, totally without meaning, but which, when once the key is obtained, presents a succession of harmonies ever new and varied, but so beautiful in their variety that the beholder or listener never wearies. The photographer, without a knowledge of chemistry or optics, is like the man who plays upon an instrument without a knowledge of music, or rather like the man who talks, but cannot read. He knows collodion is collodion, but ask him to spell the word or point it out when he sees it in print, and he stands mute and helpless. We long, however, for the time when, instead of standing up a dunce, not knowing all our letters, we shall be enabled to read the language of chemistry with a fluency that shall be as prefect as that of the accomplished musician when he glances over the sheet of music, or with the same ease that we would read an ordinary book.

That this time will come we do not doubt, let us use our influence to bring about its speedy approach. It is possible to make photographic societies more educational in their effects. Let us all do our utmost, and the difficulties will soon vanish. We look upon the efforts in this direction as stepping-stones to something still higher.

If the isolated labours of patient men have done so much for photography, what may not be accomplished in the future, when every earnest photographer is a tolerable chemist, understanding well the uses of the tools placed in his hands. There is no limit to the possibilities of the future. If single men have done so much in clearing up the mists which enveloped photography in its infancy, and which are by no means entirely dispelled now, what may not a body of patient workers, made up of different organism —the sceptic, the enthusiast, the wary lover of proven facts, and the brilliant theorist—what may not such a body do, composed of such opposite materials, but all actuated alike by a deep devoted love of photography. We can place no bound to the future. The wild dream of to-day becomes the common-place fact of to-morrow. But a few years ago we had a lord, one of whom England is justly proud, ridiculing the insane notion of burning smoke at the end of a long pipe, and yet to-day the thing is so common that we never bestow a thought upon it.

We ardently long for the time when there shall be a photographic society, so high in its standing, that wealth shall have no key able to unlock the door; and when only those can gain admittance who have proved themselves worthy by their known attainments. The members of such a society might, with just and honest pride, then write F.P.S. at the end of their names.

The formation of the classes we have mentioned would be a step in the right direction, and would tend to make this dream of the future a bright reality. Gentlemen, our prologue is over.

TONING PRINTS ON PLAIN PAPER.

BY OSCAR J. WALLIS.*

[The following paper accompanied a fine collection of reproductions of photographs, which were presented to the Society. They consisted of Kaulbach's drawings, illustrating the female characters of Goethe which were never

* Read at a Meeting of the American Photographical Society, November 11th, 1861.

engraved, but were instead, photographed by M. Albert, of Berlin. If our memory serve us correctly the original drawings were in crayon monochrome, and an anecdote is told illustrating the exquisite truth of the reproductions by M. Albert, which states that the very touch and effect of the crayon was so accurately rendered that it was almost impossible to distinguish them from the originals without touching the surface to feel if it were chalk. The artist seeing a person applying this test one day to a picture in his studio, snatched it away, saying that such fingering would spoil a crayon picture. It turned out, however, to be one of the photographic copies which deceived the master himself at first glance. The original photographic copies sold at three guineas each. Mr. Wallis, in a letter to the *American Journal of Photography*, states that he succeeds much better with the alkaline gold bath for plain paper than he did with the old hypo and gold bath.—Ed. Photographic News.]

The prints are on plain paper, that is, Saxe paper, prepared according to Hardwich's formulæ—

Water	1 ounce
Chloride of ammonium	5 grains
Gelatine	1 ,,

I float the paper according to thickness, from one to three minutes.

For silvering I use ammonia-nitrate of silver of the strength of—

Nitrate of silver	1 ounce
Water	10 ounces
Nitric acid	½ drachm.

The solution is brushed over with the well known Buckle's-brush. As to printing, I do not consider it sufficient to have the paper prepared all right; the negative has also to be a certain intensity, one that will take from three to five minutes to print in strong sunlight, and will then give an impression with the highest lights clear and the shadows bronzed.

The negatives from which the accompanying impressions were taken, all print in from four to five minutes in sunlight.

The following operations have all to be done in the *dark-room* by candle light

The prints are washed in running water for one hour; I then pass them into a dish with a weak solution of salt, in water, made faintly alkaline with carbonate of soda. (If too much carbonate of soda is added it removes the size from the paper, makes the impressions sink in the water and prevents an even varnishing of the finished prints with gum arabic.)

After remaining in this dish about thirty minutes the prints are singly taken out into the toning-bath, consisting of—

Water	1 quart
Sol. of auro-chloride of sodium	6 to 8 drops
,, carbonate of soda ...	,,

The auro-chloride of sodium I prepare myself according to the formulæ given in the *Revue Photographique*, and also in the *Notes*, and save at least sixty per cent. by doing so instead of buying it. I do not crystallize it but leave it in solution and use it as above, after adding water to the concentrated solution until it has a light golden colour.

To get fine tones, the print should be toned in from five to ten minutes, I generally take out every 8th proof, adding another before taking out the next. In this way a large number can be toned in one hour. Every proof is immediately rinsed and then left in running water until all are toned. The gold solution is preserved in a bottle and poured off from the sediment into the dish, adding gold and soda each time it is used. All the prints are now again changed into a dish with water, from which they are then taken singly or in small numbers into a solution of hyposulphite of soda, which I make as follows:—

Saturated solution of hypo	1 pint
Water	1 ,,

The print appears perfectly fixed almost as soon as passed through the solution, but I generally leave it in about five minutes. The prints are lastly washed in running water, from two to three hours, according to the number; to get clean prints it is necessary to wash the fingers well from hypo before touching unfixed ones.

As soon as the hypo solution begins to colour or deposit, I pour it into the residue, and use fresh solution in its stead.

It has been said that proofs done in this way were also toned by silver or sulphur because they improved in tone after leaving the hypo bath. But this is not so. The tone *does* improve or rather look blacker, but from quite another reason. The deposit of gold commences on the surface and on being longer continued enters also to a certain extent into the fibres of the paper, but generally there remains a substratum of untoned chloride of silver which shines through the gold tone, and gives it a reddish tint, which the hypo removes by dissolving it out. It can also be noticed that on first immersion the print takes a general red tint, which, after a minute, disappears, and leaves the gold toning in its full strength, which will account for the improvement in tone.

I believe that prints toned in this way are as well washed in half an hour as in two hours. The fibre of the paper being thoroughly saturated with water before it touches the hypo, allows the fixing to be done in a few minutes, and must, of course, facilitate the washing.

The proofs are mounted and varnished with gum arabic.

THE WET COLLODION PROCESS.

BY M. JANE.

A correspondent in Belgium sends us the following statement of formulæ and manipulations as practised on the Continent, with very successful results:—

The Collodion is made according to a formula communicated to the writer by M. Wothly, and stands as follows:—

Ether (pure)	500 parts
Alcohol	300 ,,
Soluble cotton	8 ,,
Iodide of cadmium	4 ,,
Iodide of ammonium	4 ,,
Bromide of ,, ...	1 ,,
,, cadmium	1 ,,

When the collodion is intended for dry plates 1 part of pure resin (colophony) is added.

Negative Bath for Portraits.

Distilled water	1000 parts
Fused nitrate of silver	80 ,,
Iodide of cadmium	1 ,,

After standing twenty-four hours, during which time it should be occasionally agitated, the bath should be filtered, and five parts of iodine (powdered) added. This iodine remains in the bottle and facilitates the production of clean brilliant pictures with the above collodion.

The Developing Solution consists of—

Distilled water	500 parts
Protosulphate of iron	75 ,,
Acetic acid	10 ,,
Sulphuric acid	1 ,,
Acetate of lead about	3 ,,

Mix and filter. The solution may be used repeatedly and is better after it has developed a few plates. Distilled water is used because it contains less oxygen than common water, and the solution will keep longer without deterioration. The same solution without the acetate of lead gives very good results.

The Fixing Bath consists of hyposulphite of soda of from twenty-five to thirty per cent.

Intensifying. I intensify with bichloride of mercury and iodide of potassium, after the manner described in the Photographic News. If the negative be very thin and require considerably strengthening, I use the following method:—

First, apply a solution of bichloride of mercury of four per cent. until the negative becomes brown (not till it is white) and well wash.

Next apply a three per cent. solution of iodide of ammonium (that which has liberated a little free iodine and is yellow I like best), until the negative becomes sufficiently dense, and the colour of a brownish orange tint, or, what is a better printing colour, a greenish orange tint.

Thoroughly wash and cover twice with a ten per cent. solution of dextrine in water. A small piece of camphor in this solution keeps it good.

Varnish.—I protect the negative with a varnish prepared as follows:—

Benzine	100 parts
Soft copal	10 „

This is applied cold, and there is less danger of injuring the negative than with a varnish which requires the aid of heat.

For dry plates I find the same collodion excellent, and use it without any preservative. The bath is made as follows:—

Distilled water	1000 parts
Fused nitrate of silver	100 „
Acetic acid (crystallizable) ...	100 „
Iodide of cadmium	0·5 „
Iodine (powdered)	5 „

This bath is mixed in the same way as for wet collodion. The plates keep well and give brilliant negatives.

PHOTOGRAPHY IN ITS RELATION TO THE FINE ARTS.*

"Define terms," it has been said, "and controversy will cease." Unfortunately for the simplicity of this dictum the uncertain relation of well defined terms to indefinite ideas constitutes the whole difficulty. The term "Fine Art" is one of the most common to be found in the works of writers on æsthetic science: its meaning in a general sense is understood by everybody; but for any precise definition, any accurate statement of the conditions involved, any unchallengeable landmarks pointing out its extent or limitations, we may search in vain. The consideration whether photography possesses a legitimate claim to a position amongst the fine arts involves, however, at the outset, that the conditions necessary to such recognition should be defined. All art may be broadly divided into two classes, the mechanical or industrial arts, and the beautiful or fine arts. The first has reference only to what belongs to the material facts—the physical necessities of man's life. These supplied, he discovers that he has a higher nature and nobler cravings which must be satisfied. The subjugation of matter to all purposes of material use is the province of the industrial arts. The perception and embodiment of the beautiful in its various forms belongs to the province of fine art. The distinction here drawn is a broad and obvious one, and has, in effect, been universally recognized. We shall have to enquire, then, to which category photography belongs, whether it is a mechanical or a fine art.

Every work of fine art is the embodiment of a pre-existing idea in the mind of the artist. Whatever the process used, none of its products can become works of art merely in virtue of that process; its art qualities must entirely depend upon the skill of the artist. It is the artist who makes the art, not the art the artist. The time was when painting and sculpture were not known as fine arts; they were not admitted into the sisterhood of the Nine. They had not at that time, we presume, become recognized methods of embodying the beautiful. Poetry, music, eloquence, dancing and similar arts were the more natural and spontaneous expressions of man's sense of the beautiful, while the plastic and graphic arts demanded some aid from science for their satisfactory culture. The industrial arts, with science for their guide, needed to make some progress before sculpture or painting could make many strides towards perfection,—the art of working metals, the art of hewing stone, must precede sculpture; and pigments must be found and their physical properties ascertained and developed as a preliminary step to painting. Photography, the latest born of the graphic arts demands still more aid from science; but it claims not the less a position among the fine arts. Whatever of art-knowledge is required by the painter is required by the photographer; and the same order of mental powers, developed by the same kind of training, is as necessary to one as to the other. Each must have the perception of the beautiful before he can embody it. The true artist, whether he be painter or sculptor, engraver or photographer, will stamp the impress of his powers upon his work; while the mere mechanic to whose material perceptions the more subtle and higher beauties of nature have no existence, whether he use a chisel, a pencil, or a camera, will as assuredly prove that neither sculpture, painting, nor photography are necessarily fine arts.

In a certain sense, however, it may be claimed for photography that a higher culture is necessary for its successful practice than is requisite for the prosecution of any of the recognized fine arts. To the natural endowments and education necessary for a painter he must add the education and habits of a first-rate chemist, and with these he must combine manipulatory skill, neatness and order, each in their highest degree. In selecting his subject, his point of view, his time of day, and mode of lighting, he must exercise the judgment and taste of a painter. This done his optical knowledge must decide the form of lens best suited to the perfect rendering of his subject. And now his results depend upon a series of chemical manipulations of the most exquisitely delicate kind.

As regards the art itself, then, and the amount of skill and culture necessary for its successful practice, there is nothing to derogate from the claims of photography as a fine art. The question resolves itself into one of results. These entirely depend upon the artist. The rough sketches of a Raphael with a piece of charcoal are treasured as works of art, because they give expression to the beauty of form in the mind of the artist. The true artist produces true art, no matter what his vehicle of expression, and the first ranks amongst photographers are already filled up by men who have been associated with art before they practised photography; such as Bedford and Wilson, Lake Price and Rejlander. The new art needs, however to be wielded by such men in order to receive recognition, for photography cannot create or idealize. It is not an imaginative art; it must be literal. It must deal with the actual; the world of imagination is to it a *terra incognita*. What it sees of beauty or deformity it uncompromisingly depicts and nothing more. "But for Apelles," Ovid remarks, "Venus would still have remained concealed beneath the waves," and to photography the goddess still remains invisible; what its eye hath not seen it cannot depict. It cannot refine the vulgar or give freshness to the commonplace. In all ages painters and sculptors have secured the most perfect and true types of beauty by judicious selection and harmonious combination from many models; but if photography cannot combine, it may still aid high art by the contribution of fragmentary truth; here however, its sphere in the domain of high art ends.

All this may be admitted without hesitation; but it in nowise affects the question at issue. "True art," remarks an able writer, "has two legitimate divisions: high art and common art. The former includes all work which renders the spiritual—which appeals for its interpretation to the soul; the latter comprises merely the faithful representation of natural objects. Genius guides the first; for the second, industry and clever imitation are sufficient." In the highest

* From the *London Review*.

ranks of the second division here described, photography may claim a place. Correctness of drawing, truth of detail in a degree unapproachable by the nicest manual skill, absence of hackneyed conventionalisms, are at least amongst the merits of all photographs of average excellence, while in portraiture photography may unhesitatingly claim pre-eminence. Undoubtedly there is more truth, more character, more vraisemblance in a portrait by Williams, Claudet, or Mayall, than was to be found in nine-tenths of the "portraits of gentlemen" that have for years past hung on the walls of the Royal Academy. In fact, wherever literal truth, accurate detail, perfect imitation is of value in art, there photography takes honourable prominence, for the most painstaking pre-Raphaelite may emulate in vain its wondrous precision.

As regards the reproduction and multiplication of works of art, photography may, unquestionably, in many respects claim precedence of engraving, which is nevertheless, recognized as a fine art, and admitted within the walls of the Royal Academy. In the reproduction of the works of the great masters, for instance, not only is the drawing rendered with unerring truthfulness, but the very touch, the precise handling is reproduced.

Photography must nevertheless be admitted to be an art *sui generis*. It is more allied to science than any other of the graphic arts, and in some of its most beautiful phases it becomes a scientific process, scarcely dependent for its results upon any kind of manual, still less artistic, intervention.

The recent controversy between her Majesty's Commissioners and the Photographic Society regarding the classification of photography in the forthcoming International Exhibition, has illustrated, for the first time since the birth of the new art, the importance of having its position accurately defined. Recognized art authorities do not admit photography to be fine art; that was to be expected. On the other hand, photographers disclaim the mechanical position. The Commissioners decide on a happy compromise: they offer to photographers a separate department, a kind of neutral ground. The question is not whether photography is a fine art *per se*—neither painting nor sculpture can make that claim—but whether it is capable of artistic expression; whether in the hands of the true artist its productions become works of fine art. This photographers have to prove, and await the decision of one of the largest juries ever empanelled since the world began. There is one other question the Commissoners have yet to deal with: how will they modify the position of photography in the catalogue? They can scarcely leave it in its present companionship.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 11*th December*, 1861.

The arena of photographic book illustration is steadily enlarging, and with results increasing in interest and importance. M. Gide has lately published a work on "Mexican Antiquities," photographed by M. Charney. The curious and interesting relics of an ancient civilization present themselves under a new aspect when delineated by the photographic art, and may now be said to be represented in all their integrity for the first time, for with whatever care the artist may have executed his task, truth in detail, it is now evident has been disregarded to a great extent.

Another work of the most splendid character has just been issued by M. Gide; one in which photography also performs the part of illustrator. It is entitled "*Tresors d'art de la Russie Ancienne et Moderne.*" It consists of two hundred photographic views representing the most important architectural structures of the vast Northern Empire, with their interesting details, and the treasures of all kinds contained in them. The photographs are executed by M. Richebourg, the text is by Theophile Gautier, a most competent critic in matters of art, whose taste and erudition qualify him to study a country as a museum.

M. de la Blanchère has just published a *Monographie du Stereoscope.* It is divided into nine parts, viz.: 1. History and Discovery. 2. Modifications, Improvements, and various Constructions of the Instrument. 3. Different Theories of binocular Vision. 4. Of the Material. 5. On the production of Stereoscopic Pictures by Photography. 6. Of Negatives. 7. Of Processes in which Films are Superimposed, and of Dry Collodion. 8. Positive Proofs. 9. Various Apparatus connected with the Stereoscope. This table of contents is sufficiently extensive and inviting to induce the reader to anticipate a very comprehensive treatise on the subject, and the perusal will not disappoint him. The work has been executed with conscientious care, and, as might have been anticipated from the author of one of the best treatises on photography extant, it has all the clearness and precision of a practical operator and practised writer. The book is amply illustrated, and may be considered as a timely addition to photographic literature.

On and after the 1st of January next, photographs may be transmitted by post between France and Algeria and the United Kingdom and Malta, at the rate of thirty centimes for each packet weighing under 120 grammes, or about three pence for a package not exceeding two ounces in weight, which must be open at the ends, and not contain any letter or note of the character of correspondence; if this condition be not complied with the package will be charged full letter postage. A special stamp will be provided for packages of this description, bearing the initials P. D.

M. Passeur has published the results of his elaborate investigations into the nature of the yeast of beer, which may be thus summed up:—

1. Beer-yeast is not a perfect vegetable, but rather, a mass of spores, which are produced not only in this liquid, but also in the urine excreted after the injection into the stomach of beer in sufficient quantity for this production to take place.

2. These spores hitherto designated improperly by the names of *Torula* and *Cryptococcus cerevisiæ*, are susceptible of giving birth by way of generation, to a mycelium erroneously regarded by Desmazieres as a particular species of Mycoderm, *(Mycoderma cerevisiæ)*.

3. To the phase of the *Mycoderm* there succeeds that of fructification, that is to say, the production of the *Penicillium glaucum* of botanists.

4. The yeast of cider or malic yeast, presents, in its origin and development, phenomena analagous, or rather similar to those described in studying *cerevisiæ* yeast (of beer).

5. The origin of these yeasts, and probably, also of all the others, is spontaneous.

It is known that M. Pasteur has been for a long time carefully investigating the phenomena supposed to indicate spontaneous generation, and his conclusions are, that no facts exist to warrant the supposition of such a phenomenon. His researches into the nature and origin of yeast, formed an element in the enquiry, and as all his experiments were repeated by M. Musset, at Toulouse, at a distance of 250 leagues from Paris, and with precisely the same results, they assume an unquestionable authority.

FORMIC ACID IN THE DEVELOPER.

Dear Sir,—In the Photographic News of to-day, I notice that you have published an extract from a letter of mine, respecting the use of formic acid in the developer. Either I or the printer must have made a great mistake in the quantity of acid to be added. It should be one drachm, not one ounce, of formic acid to each six ounces of ordinary iron developer.

Perhaps this would be as well corrected, to prevent searchers after detail making a mess of their pictures.

I use the following developer:—

Take protosulphate of iron	...	1 ounce
Spirits of wine ...	...	1 „
Distilled water ...	...	40 „
Dissolve, and add		
Commercial acetic acid ...	...	1 ounce
Nitric acid	...	15 minims

I sometimes keep this for months without apparent change in its working or colour. It gives good whites in positives, and soft clear detail in views for intensifying. The three specimens I sent you a few weeks since were developed with it. I have sometimes tried half the quantity of glacial, instead of commercial acetic acid. Without any counterbalancing advantages, this gives yellower whites, and turns red and very slow after about two weeks. I am very particular in cleaning my plates and keeping all my bottles clean and tidy, and I never have any stains. I am inclined to attribute these always, if the plate is kept out of white light, to careless manipulation. But I am occasionally annoyed with one or two, or a small group of transparent spots in the upper part of the picture. The annexed group* spoiled an otherwise good view, taken a few days since. I always dry out the dark frame with blotting paper, and put dry paper at the bottom and top of the plate; in spite of this and other precautions, when the spots do appear, I have often found run over two, three, or four plates and then disappear, apparently as they came, without reason. I find some of my friends have had precisely the same trouble without being able to find a remedy. Can you kindly help us to one?—I remain, yours respectfully, STEREO.

Wigdon, Cumberland, December, 7th, 1861.

WAXED PAPER PROCESS.

DEAR SIR,—It is quite refreshing amid the fumes of collodion to see in the pages of the NEWS some notice of Waxed Paper, and, as an old practitioner with it, I am quite prepared to endorse the remark of your correspondent, who says, "I must confess myself astonished that this method is not more generally practised, for the results may favourably compare with those obtained on glass." For portraiture it certainly cannot compete with wet collodion, but its effect in landscapes, especially if large, are, to my eye, even more pleasing than those produced on glass; the difference appearing to be, that whilst proofs from glass negatives may be compared to engravings, those from paper more nearly resemble drawings by an artist. At the Exhibition in Manchester during the meeting of the British Association, there were, I am told, some excellent examples of pictures taken by this process, and it is to be hoped the coming display in London will also show its capabilites. Its chief disadvantages are, the length of time required for exposure and for development, but, as respects the former, it may successfully compete with dry plates, and the latter is usually completed in forty or fifty minutes, and can always be deferred to a convenient opportunity. When lately operating in the country with a friend who used the tannin process on glass, it was found that for the same subjects he required fully as long an exposure as myself, whilst, as regards convenience, I had a decided advantage, my entire "*impedimenta*" being my camera, a folio of sensitive papers, and a black bag for changing them.

After numerous experiments, I now employ a slight modification of Sisson's turpentine method, and seldom fail in procuring a good negative. A *spoiled* proof from one taken during the summer is enclosed, which will, I think, justify these remarks.—Yours truly, ALIQUIS.

Dec. 6, 1861.

* The spots in our Correspondent's letter have the appearance of oval or pear-shaped splashes, the size of a peppercorn.

Photographic Notes and Queries.

REMEDY FOR SPLITTING OFF THE FILM.—REMOVING BADLY MOUNTED PRINTS.

SIR,—If your correspondent, "A Perplexed Amateur," will turn to vol. 2, p. 263 of the NEWS, he will find an *unfailing* remedy for splitting off the film, as well as for the creeping up and contraction of the film in drying.

If, however, he has not the number at hand, perhaps it may be as well to repeat it.

Make a solution of transparent gelatine, two or three grains to the ounce, filtered whilst hot, keep this by the fire, and pour a small quantity over each plate whilst wet, and the plate will dry evenly, and the film adhere firmly to the glass even where a tendency to warp had shown itself during the development, it is equally applicable to the wet or dry processes, and the plate can afterwards be varnished as usual. The same solution forms an excellent medium for colouring glass positives with powder colour, being applied in the same manner. We have used it for both purposes, more than four years, *without a failure in either case.*

We observed that at a recent discussion at the South London Photographic Society, some gentlemen expressed a doubt of the possibility of removing a badly mounted photograph, where starch had been used. If they will try the following plan they will find no difficulty whatever, whether the print be mounted with starch, paste, or gelatine. Place the print face downwards in a large dish (a common table dish answers well) and pour *boiling* water over the back till the print is quite covered, let it remain a minute or two and then raise one corner of the mount slowly and it will come away leaving the print in the water. If the print be properly fixed, it will not receive the slightest injury by this method of treating it.—Your obedient servants, H. and J. WALTER.

Lyme Regis, December 5th, 1861.

P.S. We must appologise for not having sent the remedy sooner, but must beg to be excused on account of being prevented by business, but, "Better late than never."

CLEANING A TIN STILL.

SIR,—A correspondent in the NEWS of the 29th November, *Sigma* can clean his tin still by pouring into it a mixture of four parts water, one part sulphuric acid—which will dissolve out the oxide of iron—afterwards a weak solution of soda or potash rinsing out well at the last with rain water.—Your obedient servant, CHURK.

December 6th, 1861.

PHOTOGRAPHIC EXCHANGE CLUB.

DEAR SIR,—I highly approve of the present arrangements of the Club, but think there is a point or two on which a little more may be said, for instance, I send a parcel of prints requiring two postage stamps, enclosing, according to directions, two more for return, thus leaving no margin whatever for other incidental expenses, would it not be better to say, "enclose one stamp more than will be required for return."

My parcel of prints came to hand yesterday, a portion of them mounted, thus requiring three stamps for postage, only having sent two I am thus indebted to the secretary.

Having received mounted prints, am I under any obligation to return others mounted or not. If I understand the rules aright, that is optional.

I would suggest that where prints are to be reversed, contributors simply write, to be cut, and where not to be reversed, not to be cut; I think we should be less likely to make any mistakes, than when making each half right or left.

I beg to express my gratitude to yourself and co-partners for the time and pains you are taking for our benefit, and shall be happy if our thanks can be allowed to assume a more tangible form than mere words.—Yours &c. J. H.

[As persons sending mounted prints cannot be guaranteed mounted prints in return, so members receiving mounted prints are under no obligation to send mounted ones to the secretary in return. It would be better if all members would send unmounted prints. It is of course unfair that the secretary should be put to personal expense as well as trouble. We are glad to record that the new arrangements give general satisfaction.—ED.]

Talk in the Studio.

The International Exhibition.—The *Times* says, "Just now intending exhibitors are very anxious about their allotments of space, and the Commissioners' office is daily inundated with letters of complaint or remonstrance on the subject. We are requested to state, therefore, that the spaces are now in course of allotment with the utmost speed that the whole Staff at the disposal of the Commissioners can work them out. All the allotments will be complete and issued to the exhibitors by the 15th of this month.—[We doubt whether it will be possible to carry out this intention with regard to the allotments in the photographic department, seeing that the Committee for undertaking the matter has been so recently established.—Ed. Photographic News.]

Card Portraits and "the Trade."—The various manufacturers and dealers connected with the photographic trade complain that the mania for card portraits has seriously injured many of the commercial branches of the art, as neither cases, passe partouts, nor frames are required for these miniature portraits. One Birmingham house, who used to employ 150 persons regularly in the manufacture of miniature cases, has dismissed all but 25, who are not fully employed.

Newcastle Photographic Society.—The usual monthly meeting of this society was held on the evening of Friday last in the Weaver's Tower, Newcastle-on-Tyne, Mr. J. C. Warren in the chair. Dr. Lockhart read a paper by Mr. Sutton, describing his panoramic lens and the manipulations with curved glasses. The subject excited considerable interest, and votes of thanks to Mr. Sutton for his paper, and to Mr. Ross for the apparatus he had forwarded for the inspection of the society, terminated the proceedings.

The Robbery of Photographs. &c.—*Francesco Bianca*, an Italian, was brought up on remand, at Marlborough Police Office, for stealing about £100 worth of valuable photographs and pictures from M. Camille Silvy, photographic artist, 38, Porchester-terrace, Bayswater. Mr. F. H. Lewis, barrister, appeared to prosecute, and Mr. Fernand Strauss interpreted. It appeared that prosecutor employed about forty men, and prisoner was overseer. He carried the property away at different times, and gave it to other parties to dispose of. He was fully committed for trial.

To Correspondents.

J. White.—The best mode of giving permanency to the re-touched parts of negative, is to varnish after re-touching. It is important to varnish first to prevent injury to the film; and after the touching out is finished, varnish again.

W. L. C.—We do not quite understand what you mean by collodion positives turning *red*. Do you mean red by reflected or transmitted light? If the former, we have never met with the occurrence; if the latter, it is what is known as red solarization, and may arise from the condition of the collodion or the nitrate bath, the presence of organic matter in either, tending in some states of light to produce it. A slight trace of citric acid in the developer will often remedy it.

Photograph.—The Photographic News Almanac will be ready on Friday, Dec. 13th. There is another Photographic Almanac, published by Mr. Greenwood, which is announced to be ready at the beginning of the year. 2. The only Photographic Dictionary, except that published in our own pages, is Mr. Sutton's, which is out of print. 3. There are many houses who will supply you with good photographic apparatus, but we cannot recommend any especial firm in these pages. 4 The largest photographic paper usually made is the *Saxe*, which is 23 in. by 18 in.; *Rive* and other papers are 22½ in. by 17½ in. Extraordinary sizes are made for solar camera pictures, of almost any reasonable dimensions.

Latent-Grateful.—It is impossible to give even an approximate idea of the exposure you will require; all the circumstances of each case will so materially modify the question. The exposure with the full aperture of your Ross 5 in. by 4 in. lens for a portrait, the sitter being 9 or 10 feet from the lens, with good bromo-iodized collodion and iron development, good light, in the open air, might be about 5 seconds If in a glass-room, it would depend entirely on the amount of light. Whether a fair person or a dark person, whether dressed in white satin or black velvet, and a variety of other circumstances, will all materially affect the question. You may ascertain better by one trial than we can tell you by a dozen guesses at the conditions of the case.

R. G.—We have never tried a rolling press instead of a lithographic press for mounting after Mr. Stuart's method, but think that with certain precautions it might answer. We will try shortly.

G. H. C.—The bichloride of platinum solution, recommended by Mr. Maxwell Lyte for intensifying, should be applied after the negative is fixed. It is most suitable for pictures requiring a slight amount more vigour or brilliancy, but not much greater thickness or density.

John Frankland.—The design, No. 4, for a glass-room, in the third volume of the News, will be most useful for general purposes. We should prefer a little more glass in it for our own use, and instead of three feet at the roof and sides of the background end, without glass, we should recommend six feet. A few feet longer and wider would also be an advantage. The other design to which you refer is in some respects good, but it would admit insufficient light for many purposes, and would also require some modifications in detail.

W. G. Barnett.—We are obliged by your courteous and logical letter, which, although scarcely suited for publication, we will treasure in our private collection for the perusal of friends. We shall have pleasure in complying with your request.

Tyro.—The charges named in your note appear to us to be perfectly reasonable.

C. E. L.—The proportion of acetate of soda we prefer for our own use, and find quite successful, is 30 grs. to 1 gr. of gold. If you get an acid sample of gold, just barely neutralize it, and no more, with carbonate of soda. Whilst acetate of soda is slightly alkaline, it is not sufficiently so to neutralize any appreciable amount of acid in the gold.

Photogen.—The white fire, or "photogen," is burnt in a lamp made expressly for the purpose, which is patented. Before attempting to construct any apparatus for the purpose, you should get a copy of Mr. Moule's specification, so as to avoid infringing his patent.

An Amateur in Positives.—We know nothing of the process of M. Dubois, but what has appeared in our pages. The Niello paper is to be had of various dealers.

Justitia.—There is no simpler or better mode of recovering the silver from waste solutions, when old hypo baths form part, than that by means of liver of sulphur. It does require time, but it should not be expensive. To adopt other methods the various solutions should be kept apart, and different methods employed with each, which would be more troublesome, unless there were large quantities of each solution.

W. Bartholomew.—We have not yet had an opportunity of trying your dry plates, but hope to do so shortly. You have certainly been active in the matter. Next week you will find a suggestive article on dry processes in the News, which will probably interest you. We think dirty plates the most common cause of split films.

Tit Tat To—In our next.

Quasimodo.—The present volume will be completed at the end of the year. 2. We have never used the collodion filter, preferring to let our collodion clear by subsidence, but we are told that the filter answers. 3. The best mode of dealing with your old collodion is to mix it with some quite new. To add bromide to it dissolve bromide of cadmium in the smallest quantity of alcohol you can, taking care to know the exact proportion, and then add sufficient of the solution to the collodion to introduce one grain of bromide in each ounce of collodion.

H J. W.—See recent letters on the Splitting of the Film, and especially our note to the letter of E. E. L. in last week's "Notes and Queries." Your booth is of somewhat too limited dimensions, especially in height; it should be not less than nine or ten feet high. With the proposed dimensions you will have only eight feet at the roof and sides to admit light, and as that has to be covered with a semi-transparent cloth, we fear you will have too little light on your sitters. The Photographic News Almanac will be ready on Friday, Dec. 13th. All persons who have sent stamps will be supplied within a few days

T. P. E.—We are sorry for your trouble, but cannot unfortunately enter into the legal rights of the matter. Your course should be a very simple one; lay your complaint in writing before the Board of Health. They are bound to remove or prevent any illegal nuisance. They will determine how far it is within their power, and will, if they can, doubtless find a remedy for the wrong you suffer.

J. F. Ward.—We are obliged by your communication and the prints. We shall esteem it a favour if you will furnish us with details of your formulæ and manipulations, as we shall have something to say on the subject in our next.

Teesdale.—We have for years past obtained transparencies by camera printing, both for the stereoscope and other purposes. If you state your difficulty clearly, and describe your apparatus, we will help you with pleasure. In producing transparencies for the stereoscope, you must of course have a division between the two halves through the entire length of the copying box, otherwise you will have, as you describe, the two images overlapping each other on the ground glass. Your suggestion regarding the Exchange Club shall receive attention.

W. G. W.—The white turbidity and deposit in your toning bath is chloride of silver, and, possibly, if you use common water in making the solution, carbonate of silver, arising from the fact that you have not removed all the free nitrate from the print by washing previous to immersing it in the toning bath. The print should receive three washings of about 5 minutes each previous to toning. The deposit, although troublesome, is not, however, the cause of your failure. The prints received are imperfectly fixed, and show decided traces of decomposition in the hypo, which is either used up, or has become decomposed by the prints containing acid. Your sample of chloride of gold has probably been very acid, and in that case the prints would decompose the hypo, and produce the results you forward. See answer to C. E. L. It is better to keep separate baths for plain and albumenized paper.

A. B. C.—Your table of equivalents must be wrong, or else you have misquoted it The equivalent of iodine (I) is 126·5, and of potassium (K) 39·15, making altogether 165·65, which is the equivalent of iodide of potassium (IK). In like manner the equivalents of the iodides of ammonium, sodium, and cadmium are 144 5, 149·5, and 182·5, respectively. Thus, 144·5, say grains, of iodide of ammonium, 149·5 of iodide of sodium, 165·65 of iodide of potassium, or 182·5 of iodide of cadmium, each contains the same quantity of iodine, namely 126·5 grains; from this you may readily calculate that each grain of the several salts will contain about ·87, ·84, ·76, and ·69 grains respectively, of iodine. Tables of equivalents vary slightly. You will find one in the Photographic News Almanac for 1862.

Aliquis.—By the "approaching exhibition" we presume you mean the International Exhibition of 1862. There is no announcement as yet as to the time when contributions must be forwarded. The Photographic Society will not have any exhibition during the coming season.

Several correspondents in our next.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to 32, Paternoster-Row.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 172.—*December* 20, 1861.

PHOTOGRAPHY AND CONTEMPORARY LITERATURE.

If, by some singular combination of circumstances, it could occur that some centuries hence photography should have become one of the lost arts, and if, at the same time, it could happen that no vestige of a photograph remained in existence, future generations of the world would, we venture to affirm, still have a most perfect and vivid idea of the capabilities and productions of this wondrous art. This idea would be preserved to them with the utmost completeness in the thousand and one passing allusions in contemporary literature, in which the art has become a standing illustration of rapid delineation, and the term photograph a synonym for most perfect, minute, and literal accuracy. Is a description of life and manners striking for its minute and graphic truthfulness? It is at once regarded as "photographic in its unerring accuracy." Is a vivid, forcible, and detailed impression of any scene or narrative received? It is said to be "daguerreotyped on the mind." Is a painting remarkable for its delicate and perfect drawing, and absence of the characteristics of conventional art? It is pronounced "photographic in its rendering of minutiæ." In a variety of forms, and an infinity of instances, the truth, the beauty, and the usefulness of the art receive constant and unpremeditated recognition.

This unconscious appreciation, this indirect and almost unintentional acknowledgment—which is by far the most valuable—is almost invariably honourable to photography: and the hearty, ungrudging recognition of some of the better writers on art subjects is not less so; but it unfortunately happens that every now and then, at intervals, a tendency or feeling creeps out and finds expression in some portions of the press, which displays an ignorance so dense, or a grudge so transparent and preposterous, that whilst we may understand its origin, we wonder how it found any chance of publication. Several such manifestations of feeling have found expression recently. It would almost appear as if the fifth-rate artists, whose occupation has long been well nigh gone, were, in anticipation of the challenge which photography will give at the forthcoming exhibition, gathering up their powers for a final effort to crush the art, and were beginning by a series of side-winds to throw contempt upon its productions. We feel it important to keep our readers informed of such attempts, and, at the same time, to rebut emphatically the false charges so often promulgated.

The first case to which we have to advert occurs in the *Athenæum*, a journal which has often rendered graceful tribute to photography and photographs, but which in a recent number offends in two instances; in one case casting a passing sneer on the art, and in the second shows a sad ignorance of the productions of English artists. In a review of a recent work by Mr. Thackeray, the writer thus commences:—

"There is a superstition amongst many people that photographs are likenesses, and that, however hideous the result may be, the photograph only brings to light the ugly possibilities that lie dormant in the individual. Again, there is a notion that caricaturists produce the strongest likenesses; it being essential to the success of caricatures that every one should 'recognise them at a glance.' In both cases candid friends mildly insinuate against the 'vanity' which protests against accepting the award. It is always easy to understand a dashing exaggeration; it saves trouble both to the artist and the public, and spares the skill and patience necessary to produce or to discern the delicate shades of the *poco meno e poco piu* needed to make a genuine portrait. What is true of portrait-painting holds good of the art of delineating character. It is easy to produce a caricature which, by its exaggeration of some salient peculiarity, is certain to be recognised—and to raise a chuckle of recognition from its trick of resemblance to some people we have seen and observed; but that does not constitute a knowledge of human nature. Mr. Thackeray's present work—the sad failure of a man of genuine powers—seems to us to be in Literature what a photograph or a caricature is in Art."

Now we utterly deny the truth, justice, or good taste of this allusion to photography. We deny that photography necessarily or in itself possesses anything in common with caricature. "Dashing exaggeration of some salient peculiarity" is precisely the thing which photography is incapable of. Even in bad photography, where exaggeration may be detected, it has no power of discriminating between "salient peculiarities" and common-place features. Moreover, "the delicate shades," &c., needed to make a genuine portrait, are in reasonably good photography, the very points of its acknowledged excellence, rather than its glaring deficiency. In the same number which contains the review, we find the following:—

"The London Stereoscopic Company have issued among their later enterprises, a series of instantaneous views of Paris—of buildings, boulevards, street-views and the like—taken, we infer, by French artists. They are extremely sharp, vivid, brilliant, full of life and motion; the very image of the actual places and events transferred and fixed for ever. We have recently been looking over a good many French and Italian photographs; and we must warn our English friends, that in the coming contests at South Kensington, they must look for stern trials of strength. The French artists have the advantage over us in marine and street subjects; the Roman and Venetian artists in landscape and structure. Our figure photography is, perhaps, superior to the French or the Italian."

Most of our readers are aware that the stereographs referred to are by Mr. William England, an able English photographer; but in the spirit which depreciates home productions, the writer "infers" they are by French artists. Quite consistent with this inference is the statement that continental photographers excel in marine or landscape photography, and that English artists are superior in figures.

These slights and errors are mild, however, compared with those we find in a recent article, entitled "The New Picture Galleries," in the *London Review*, which is so amusing in its preposterous mis-statements, that we have transferred it in its entirety to our own columns, where it will be found in another page of this number. The *London Review* stands so high as a calm and truthful exponent of art and science, and has so often been distinguished by excellent articles connected with photography, that we were deeply grieved and disappointed to find what appears to be the spiteful lucubrations of a disappointed artist in its columns, which but a few weeks before had contained an article striking for its dispassionate and fair statement of the relation of photography to the fine arts.

The first characteristic of the article in question is its *malus animus*, its spiteful motive; the second, its false reasoning; and the third its gross ignorance. The first is shown in assertions and allusions, which both the writer and everybody else know to be untrue. In such phrases as "distorted by the painful process of photography," "sufferings in the inferno of some eminent photographer," "disfigured appearance of a friend," such as might be sought for "in a morgue," and other allusions equally choice.

The false reasoning is strikingly illustrated in such arguments as the following :—

"A photographic likeness cannot be true, as will appear from the consideration that it is the result of one momentary isolated impression, and not a careful generalization. If a person who had only known us for one day were to undertake to draw our character, the odds are as Lombard Street to a China-orange that he grossly misrepresents us. Or again, if he were to describe our person, dwelling almost entirely on one feature, or one attitude or habit, we should complain of being caricatured. And this is the inherent fault whereof we accuse photography; it caricatures.

Because then a person who had known us but for one day would, in describing us, probably misrepresent us; because a person describing our person and dwelling entirely on one feature would caricature us, *ergo*, a photographic portrait cannot be true and must be a caricature! The conclusion follows upon the premises with a vengeance! Is it necessary to point out how utterly incomplete and imperfect are the analogies the writer attempts to institute between intangible "character" and definite form? The man who should attempt to describe character from a day's acquaintance, would be attempting to do what the writer states photography does not do; to "generalize," and to generalize from insufficient details. If, instead of generalizing from the knowledge gained during the acquaintance of a day, the person referred to simply and truthfully reported the history of the day's intercourse, he would neither misrepresent nor caricature. Photography does not attempt to do what many many artists attempt, and either do badly or entirely fail in effecting; but it gives a truthful presentment of what it sees and nothing more. It may only illustrate one phase of character, give one expression of face, and that expression may or may not be the usual and characteristic one, but it is not, and cannot be unless the photographer be wretchedly incompetent, or the sitter unaccountably perverse, a caricature. The allusion to the portrayal of only "one feature," &c, is simply meaningless.

We are next told :—

"A good portrait-painter studies carefully the subject of his picture, endeavouring to live awhile in his company, draws him into frequent and free conversation, marks his habits and looks under various circumstances, gathers up all the particulars of his individual appearances, and then unites and combines them in one great general resemblance."

It is no part of our business or inclination, in defending photography, to depreciate the portrait-painter; but we appeal to all who know anything whatever of the subject, as to the truth of this statement. That the few—the very few—who have made great names in portrait painting have aimed at such generalization, we will admit; but that the ninety-nine out of every hundred portrait painters—the ruck whom photography has superseded—either aimed at or obtained such a knowledge of their sitters, we utterly deny; and we point to the army of pink and blue miniatures with big eyes and little mouths, and the oil paintings with brick-dust flesh and brown shadows, in confirmation of our statement. As to the results of this boasted generalization, even in great masters, let an able writer in the *Cornhill Magazine* speak. Describing the prevalent taste in artists for producing the upper lip in the form known as "Cupid's brow," he says :—"Such is Raffaelle's favourite lip: he hardly ever has a face without it. One would fancy that all the people of Vandyke's acquaintance had it. Kneller is great in it; so is Fuseli. Sir Thomas Lawrence gives it with a vengeance to all his sitters—curling the curves, and making the little drop in the centre almost drip. The painters are never satisfied without it, and give it to all their heads alike—to Cortes as well as to Cervantes, to Descartes as well as to Shakespeare, to Arkwright not less than to Schiller and Goethe. What the painters do badly, the engravers do worse; and so this lovely lip is rendered vulgar and meaningless. Belonging to a few, and that few a defined class, it is represented as the common property of all." Such generalization the worst photography is incapable of effecting, whilst, regarding the best, we emphatically repeat what another article in the *London Review* recently stated :—"Undoubtedly there is more truth, more character, more *vraisemblance* in a portrait by Williams, Claudet, or Mayall, than in nine-tenths of the 'portraits of gentlemen' that have for years past hung on the walls of the Royal Academy."

Regarding the ignorance displayed by the writer in question, it is something at once amusing and astonishing, and reminds us of a phrase we recently saw used in reference to another subject, the ignorance on which was stated to be "not only very extensive and profound, but very elaborate and minute." For instance, we have the following :—

"A 'pistolgram,' as these rapid portraitures are now (especially when the subject is an infant) designated by the faculty, is taken, the subject is flashed upon paper, a momentary appearance is produced, and the result is invariably more or less a caricature."

It would perhaps be difficult to bag a greater number of errors than the writer has here brought down at one shot. Album-portraits (the subject the writer is treating of) are not called "pistolgrams" either by the "faculty," whoever that may be, or anybody else; "the subject being an infant" has nothing to do with what *are* termed "pistolgrams," they are not flashed on paper; the appearance is not momentary; and the result is not invariably a caricature. We have only five mis-statements in four lines; but at least four out of the five we charitably set down as the result simply of ignorance of the subject on which the writer comments.

We have not space or inclination to follow the writer in his mis-statements much further; but we will just advert to one more. By some chance he has caught part of an idea to the effect that the marginal lines produced by some lenses are distorted, he proceeds to "generalize," and we have the following :—

"Almost all have a cast in the eye. Others have either an unmeaning grin, or a silly smile, or a surly frown that Timon of Athens might have envied. One young lady looks saucy, another as melancholy as Mariana in the moated grange, another has such a dangerous look that Petruchio himself would not dare to marry her. With these defects in themselves, the figures stand or sit in the centre of a perfect chaos. Panels of walls, doors, jars of conservatory flowers, tables, and other articles of furniture, lean, roll, and tumble about the apartment, as if spirit-rapping was going on, in every position out of the perpendicular. The central figure may be in focus and straight, but even if she escape with no distortion, such as a monster hand or foot, or a cheek that seems afflicted with the mumps, all her *entourage* is reeling around her, as if she had been taken in the saloon of the big ship during the great storm."

It is impossible after reading these lines to escape one of two conclusions: either that the writer is making wilful mis-statements, or that he has qualified himself for writing the article by carefully avoiding any examination of the works of all photographers of ability and repute.

One more remark, and we have done. Referring to an imaginary lady, the writer says :—

"A photograph book is given her by some gentlemen in exchange for her likeness, which has just been taken by Silvy or Southwell. This may be multiplied to any extent, and every man who is in the original owner's set at Trinity or Christ Church may be favoured with a copy."

What class of society this writer can have mingled with we cannot conceive, nor from whence he has derived his ideas of the "sets" at Trinity or Christchurch; but if he imagines that respectable photographers sell to strangers duplicates of the portraits of private ladies sitting to them, or if he imagines that the students at any college get surreptitious copies of the portraits of ladies known to their mothers and sisters, to "bandy about" amongst the fellows of their set, we can only say, his notions of social obligation are as low as his knowledge of photography and art is shallow.

PHOTOGRAPHIC CHEMICALS;

THEIR MANUFACTURE, ADULTERATION, AND ANALYSIS.

THE uses to which the phosphates are at present applied in photography are not numerous; the most important being the printing process devised by Maxwell Lyte. This depends for its success upon the formation of a sensitive surface of phosphate of silver (a salt almost as sensitive to light as chloride of silver), which is, after being impressed by light, fixed by soaking in a solution of phosphoric acid, which has the property of dissolving phosphate of silver as readily as hyposulphite of soda dissolves chloride of silver. The theory of the process is perfect, and the results are quite as good as are obtained by the ordinary printing process; whilst the manipulations are no more difficult. The only point to be observed is to be careful that none of the solutions contain chlorides, this, however, is not a matter of difficulty. The necessity for the presence of hyposulphite of soda, that bane of all photographers, is also obviated, and when there is so strong presumptive evidence, not to say certainty, that to this salt we owe nine-tenths of the "dissolving views" which meet the eye on turning over a portfolio of photographs, a process which enables us to dispense entirely with hypo in any shape or form, undoubtedly deserves more notice than has hitherto been accorded to it. We have frequently had occasion to test the good qualities of this method of printing, and we think that it will confer a benefit upon our readers if we enter somewhat into the details of the manipulations.

The paper is prepared in the first place on a bath of phosphate of soda; for this purpose Mr. Lyte recommends the common phosphate; this, however, we have shown in our previous article to be inferior to the triphosphate of soda. This may be used either with or without albumen. For a salting bath with albumen, take

Tribasic phosphate of soda	... 10 drachms
Acetate of soda	... 5 ,,
Sugar of milk	... 1 ounce
Albumen	... 10 ,,
Water (distilled)	... 10 ,,

The first three bodies are to be dissolved in the water, then mixed with the albumen, and the whole beaten to a froth, allowed to settle, and strained off. The paper is to be floated on this bath exactly in the ordinary way, and then suspended by a corner to dry. We do not, however, recommend that albumen be employed in this process, as it always contains chloride of sodium, the ill effects of which will be pointed out subsequently. The bath which we have found to give the best results, is composed of—

Tribasic phosphate of soda	... 1 ounce
Rochelle salt	... ¼ ,,
Sugar of milk	... 1 ,,
Gelatine	... ½ drachm
Water	... 1 pint.

The gelatine is first to be dissolved in a little of the water, made hot, and the other substances finely powdered, and dissolved in the remainder of the water, and the two solutions mixed together. Filter into a dish, and float the paper as usual. As soon as the paper has become sufficiently damp for it to cease to curl upwards, remove it, and allow it to hang by one corner till dry. The silver bath is composed of—

Nitrate of silver	... 1 ounce
Distilled water	... 5 ounces
Acetic acid	... 5 minims

Sensitize as usual, and when dry expose under the negative in the printing frame. The exposure must be carefully regulated, and the picture removed from the frame as soon as the desired intensity of colour is attained, for it is important to be remembered that in this process the picture loses scarcely anything by fixing, so that an over-printed positive cannot be toned down in subsequent baths, without considerable difficulty. When the picture is printed to the requisite depth, it must be soaked for ten minutes in a dish of pure distilled water. It must then be transferred to the fixing bath, which Mr. Lyte prepares by adding nitric acid to phosphate of soda. His formula is as follows:—

Phosphate of soda . .	... 13 ounces
Water	... 42 ounces
Nitric acid (sp. gr. 1·32)...	... 8 ounces.

But we do not consider it advisable to form an extemporaneous phosphoric acid bath in this way, as the reaction of the nitric acid on the phosphate of soda would not (according to the best chemical authorities) completely liberate the phosphoric acid, but would form a mixture of phosphoric and nitric acid, phosphate of soda, and nitrate of soda. This phosphoric acid bath being capable of being restored to its original efficiency when exhausted, with very little trouble, it is far better to commence with a pure liquid at once, especially when phosphoric acid is so readily made. The plan which we have found to answer best, is to take one part of glacial phosphoric acid (which may be prepared by either of the methods already detailed), and dissolve that in twelve parts of distilled water. In this bath the proofs are to be soaked for five or ten minutes, or until all the yellow colour has perfectly disappeared from the undarkened parts of the picture, which should be left perfectly white. The proof is then to be transferred to pure water, where it must be allowed to soak, with frequent changes, until all the silver salt is dissolved out, which may be ascertained by allowing the proof to drain into water, containing a little common salt dissolved in it. If there is produced a white turbidity, the washing has not been continued long enough, and the print must be soaked again in pure water. When washed, the prints will be perfectly fixed, but will be of an ugly red colour; they must, therefore, be allowed to soak for a few minutes, in a colouring bath, composed of—

Chloride of gold	... 15 grains
Common salt	... 3 ,,
Water	... 30 ounces.

This bath will be found to colour the proofs very quickly. When they are of the requisite tone they may be removed, and after being washed in plenty of common water are ready to be dried. In practice this process will be found to possess great certainty, and is not at all complicated or tedious in its manipulations. The chief precaution which must be taken in order to secure good results, is to guard against the presence of chlorine in any of the preliminary baths before toning. Chloride of silver being insoluble in phosphoric acid, it is evident that if any chlorine compound finds its way into any of the baths in which the paper is soaked, chloride of silver will be precipitated on its surface, and will there remain unaffected by any of the subsequent operations. The ill effects of a neglect of this precaution are not, however, nearly so serious as imperfect removal of the hyposulphite of soda is in the ordinary process. In the former case the worst that can happen is a slight darkening of the lights of the picture after prolonged exposure to light, while in the latter case the picture fades altogether from the sight. The phosphate of soda bath must especially be tested for chlorine by adding nitrate of silver to it, and then an excess of nitric acid. If the precipitate which is formed in the first instance entirely dissolves upon addition of the acid, the bath is free from chlorine; the fixing and washing baths should be similarly tested.

When the phosphoric acid fixing bath is saturated with phosphate of silver, it may be restored to its original efficacy in the following manner:—Pour about three fourths of the liquid into a glass vessel, and add to it carefully hydrochloric acid. This precipitates the silver in the state of insoluble chloride and sets free the phosphoric acid again. The hydrochloric acid must be added gradually, and its addition stopped as soon as it ceases to form a precipitate. The remaining fourth of the old fixing solution is then to be poured in, and the bath after filtration will be fit to use again. The reason of keeping back a portion of the fixing bath is to avoid the possibility of having any unprecipitated chlorine in solution. If by chance a little excess of hydrochloric acid has been added to the larger portion of the liquid, it will be all precipitated upon addition of the small quantity kept back.

We have in the above sketch only given the more important particulars of this process; the details will be readily filled in by any skilful operator. Pictures printed in this manner have stood tests which very few silver prints would pass through uninjured, and from nearly six years experience which we have had of prints so prepared and fixed, they may be considered as far surpassing chloride of silver proofs in stability, if, indeed, they are not absolutely permanent.

MY IMPRESSIONS OF PHOTOGRAPHY IN PARIS; AUTUMN, 1861.*

BY C. JABEZ HUGHES.

There are two methods of examining the condition and progress of photography. The one, by estimating it from the examples seen in artists' galleries and specimen cases; the other, from those shown in the periodical and special exhibitions. The former will, doubtless, show the truest picture of the art as it is daily practised, and as the world generally knows it; while the latter will exhibit it in its highest excellence, and latest degree of novelty.

The every-day character of Paris photography was sufficiently alluded to in my last; its condition, as indicated in this year's Exhibition, will form the subject of the present paper.

As this Exhibition was in many respects much superior to any we have had in this country, a few words may not be out of place as to its general character, before it is alluded to in detail.

In the first place, there was abundance of room and an excellent light. A gallery of the *Palais de l'Industrie* was devoted to it, and it was a great pleasure to examine the pictures without going on the knees on the floor, or straining the neck by looking up, most of the prints being placed on the level of the eye. As our exhibitions in London usually take place in winter, and in rooms not well lighted, our pictures are principally seen by gas-lights. This latter is very deceptive in judging of the tones of prints. Many pictures of suspicious sulphury tone, of objectionable foxy tint, or of detestably slaty hue, when viewed by strong artificial light, receive a degree of credit for goodness which would certainly be denied in broad daylight. Good photographs never need the aid of artifice, and only inferior ones are improved by temporarily assuming the charms they have not. It was, therefore, very pleasing here to judge the large collection of choice prints in broad daylight, noting all the most delicate gradations of tints and tones, and thus mentally according that degree of praise to each artist as they approached one's own ideal of excellence.

The collection was very large—over two thousand—and principally contributed by French exhibitors. I should have liked to have seen more of our English pictures, especially from our landscapists. One good thing I hope our 1862 International Exhibition will do—make the clever artists of different nations better acquainted with each, so that they may more often exhibit their best examples side by side in each others countries. I hope, also, the getters-up of the future Photographic Exhibitions will deem it part of their duties to put themselves in communication with the gifted of other lands, so that all may derive a greater benefit from these annual gatherings, and that, at least, our own exhibitions may have infused into them a little more of the cosmopolitan character. I write thus, because, popularly speaking, we know so little of French photography, and because I feel that if we had more knowledge we should esteem our Gallic brethren better, and be more stimulated to excel, from observing the high point they have reached.

The landscape portion of photography was decidedly deficient in quantity and quality; and though there were many good pictures, the majority had the same faults that existed in our pictures three or four years ago, and which have since been so much amended. White paper skies, black trees with little detail, heavy shadows without transparency, water without liquidity, when tranquil, looking like chalk, and when in motion, like cotton wool. Above all, there was wanting in these landscapes that one thing, which constitutes the very soul of an open-air picture, atmosphere. In the introduction of this great requisite into their more recent works, consists the improvement of our English masters; but the craving for it has always existed amongst us, and the only question has been, how best to obtain it. Early calotype prints were valued because they suggested it, and dry plates denounced because they did not supply it, and to Mr. Mudd is the great credit awarded, that, even with dry plates, he was one of the earliest to obtain it.

Assuming then that I am correct, that the English have a keener appreciation of the beauties of aërial effects than their French brethren, (and their neglect of this class of work generally, and their frequent deficiency when they attempt it, gives me ground for the assumption,) I ask what can be the reason? That it is certainly from no inability to produce softness, their other pictures shew; and it can scarcely arise from deficiency of perception where delicacy should predominate, for nothing requires for its proper delineation so much exquisiteness of half-tone as the human head, and in portraits having this very pre-eminence they undoubtedly excel.

I have a theory to explain the anomaly by supposing that it arises from the difference of the atmosphere of the two countries; that in the dry, clear, smokeless atmosphere of France, and Italy too, there is much less than in this country, of that gauzy, fleecy vapour resting upon and overhanging and slightly enveloping all objects, particularly at a distance. I think that in our humid climate the clouds usually rest lower, are more abundant, and invest the scene with their character in a higher degree than in those countries. To this is due the fact that the atmosphere plays so important a part, and is so large an element of beauty in all our landscapes. Therefore no representation however executed is ever perfect unless this peculiarity is duly represented. So long, therefore, as our photographs ignored these aërial effects they were defective. Not only, however, do these beauties of atmosphere exist in an exalted degree in our landscapes; but there seems a peculiar fitness in our people to represent them—a sort of *genius loci* that qualifies our artists for delineating them. For many years our figure and historical painters have been working hard but making little headway, while our landscape painters have taken rank at once and continue to hold their own against all comers. In like manner, and by the harmony of analogy, while English photographers have not made such strides in portraiture, as this Exhibition clearly shows, our landscape photographers, true to their national instinct, are able to take the highest grade in their peculiar vocation. It would seem in peoples as in individuals that no one can be equally great in all things. There are no Admirable Crichtons among nations. If to the English be yielded the palm of landscape work, that of the figure must be given to the French. The landscape may have its charms, but it is too quiet and tame for the Frenchman. He delights in life, he is full of vivacity himself, and must have vitality in his subject. Look around at this Exhibition, the human figure is seen everywhere. In all sizes, forms, proportions, positions; priest and king, noble and beggar; turn which way you will, draped and undraped, in fancy and plain costume, sent by professional and amateur, it is constantly the human figure. After this, perhaps, the next most

* Continued from page 590.

numerous are the copies of works of art,—paintings, engravings, and statues, being the principal. Here, again, this passion for depicting the human form is repeated—for few subjects are painted but those that prominently represent the human figure, either in love, in battle, or religious exercises. These three conditions, variously modified, form the subjects of nearly all the pictures, engravings, and statuary. In English photographic exhibitions the portraits are usually voted a bore, and rarely form more than about one-fourth of the whole, but here there are portraits everywhere. All the dignitaries, artists, actors and actresses, editors, musicians, seem to spend much of their time in photographic *ateliers*, judging by the abundance of their portraits. There is this peculiarity, however, about the numerous portraits, that they are all interesting. It is either some distinguished person, or a popular actress in some fresh character, or there is a reason of some sort why they are there, and not simply a "portrait of a gentleman;" this, therefore, relieves what would otherwise be monotonous. Then the styles of the different photographers are so very varied, their posing so different, the arrangement of drapery and accessories so bold, original, or bizarre, that one can scarcely get tired of them. This one will produce scarcely anything but very large heads, that one makes full lengths, another has only distinguished generals, the next, perhaps, only popular performers, and so on. Properly speaking, it is not therefore so much a collection of portraits, as actually studies of the human figure, under a thousand varieties of form, expression, and costume. Our French brethren must fully appreciate Pope's line—

"The noblest study of mankind is man,"

for, at least artistically, study hard how to delineate him in every variety of manuer.

(*To be continued.*)

BURNT-IN PHOTOGRAPHY.*

BY MICHAEL HANNAFORD.

A HINT might also be got from the methods of making paste diamonds. A *flux*, or, as it is more generally here termed, *strass*, is first made, and charged with metallic oxides, as in the case of enamelling.

The following is a good recipe for preparing strass:—

Rock crystal, 1,600 grains; *borax*, 560 grains; *carbonate of lead*, 3,200 grains; oxide of manganese, ½ to 1 grain. Powder each separately, mix, and fuse in a crucible; pour the melted mass into water, separate any reduced lead, and again powder, and re-melt the mass.

As it may be desired to imitate the colour of some of the precious stones, we give the formulæ for a few of them:—

AMETHYST.—(1) *Strass*, 500 grains; *oxide of manganese*, 3 grains; *oxide of cobalt*, 2 grains. (2) *Strass*, 4,600 grains; *oxide of manganese*, 36 grains; *oxide of cobalt*, 24 grains; *purple of cassius*, 1 grain.

CORNELIAN (RED).—*Strass*, 7,000 grains; *glass of antimony*, 3,500 grains; *calcined peroxide of iron*, 875 grains; *binoxide of manganese*, 75 grains.

EMERALD.—*Strass*, 7,000 grains; *carbonate of copper*, 65 grains; *glass of antimony*, 7 grains.

GARNET.—*Strass*, 1,200 grains; *glass of antimony*, 580 grains; *purple of cassius and binoxide of manganese of each*, 3 grains.

OPAL.—*Strass*, 960 grains; *calcined bones*, 48 grains.

RUBY.—*Strass*, 45 parts; *binoxide of manganese*, 1 part.

TOPAZ.—*Strass*, 1,000 grains; *glass of antimony*, 44 grains; *purple of cassius*, 1 grain.

TORQUOISE.—*Blue paste*, 20 to 25 parts; *calcined bones*, 1 part.

Probably, for our purpose, it would be better to reduce the quantity of strass very materially, so as to get a tone sufficiently deep when only placed on in a thin layer.

By either of the above methods we may produce a compound which can be ground to powder in a mortar, and used as "enamel colour" in Joubert's process.

In the number of this journal, of the 15th ult., a process by W. J. Miers, for obtaining glass positives in gold, is given as an extract from the *British Journal*. He flushes a positive or negative with chloride of gold until maximum intensity is obtained. The plate, washed, is immersed in dilute nitric acid for a short time, then rinsed and treated with a strong solution of ammonia. This alternate application of nitric acid and ammonia repeated three or four times clears off all visible traces of the silver forming the image at the commencement, leaving a picture in gold which may be burnt-in.

The use of salts of some other metals might be tried in lieu of gold, in which case the application of nitric acid and ammonia would have to be omitted or modified.

An article on enamelled photographs, by M. A. Lafon de Camarsac, from the "Comptes Rendus," of June 11th, 1855, is given in the *Journal of the Photographic Society*, for September 21st, 1855. He operates on black and coloured grounds, as well as on white, or on transparent glass. On the dark foundations the lights of the image are obtained from reduced silver formed by developing the image in the ordinary manner until the half-tints are overdone and obscured, and the deep shades covered with a thick deposit presenting the appearance of relief. The fire cleans the image and restores all its delicacy. On white porcelain, or enamel, or on transparent glass, the deposit of silver is treated with solutions of salts of tin, salts of gold, or salts of chromium, by which means he obtains various colours, very vigorous when removed from the muffle, and presenting a peculiar semi-metallic brilliancy. A very thin layer of an appropriate and very fusible flux fixes the image on the ground.

He also produces pictures in a rather singular manner by the action of light on the salts of chromium mixed with gelatine. The exposed plate is washed in water and then placed in a muffle so as to destroy the gelatine by heat, the metallic deposit alone remaining on the plate. This is now treated with the salts of gold and of tin, &c., as above, and after being covered with a layer of flux, it is again subjected to the influence of heat.

The resins afford him the means of obtaining pictures in much the same manner as in Joubert's process. Bitumen of Judæa dissolved in essence of turpentine, with the addition of resin, after being influenced by light is no longer acted on by the solvent; exposure under a transparent positive, and a short subsequent treatment with turpentine, gives a sticky image as in Joubert's case, and enamel colour may be applied in like manner.

Some of the photo-lithographic processes could be made available for our purpose. Perhaps that of Colonel James would serve well for obtaining copies of engravings, &c., in form for burning into ceramic ware. The image might be produced in paper in the same menner as if it were to be transferred to stone, some compound containing oxides being substituted for grease.

Having recently been engaged in experimenting in this direction, so far as photo-lithography is concerned, we will put our ideas, founded on those experiments, in a tangible form. The sensitizing solution is made thus:—

Albumen	3 ounces
Gum arabic solution of about the consistency of albumen ...	1 ounce.
Bichromate of potash to saturation	

Float paper on this in the usual manner, and if the solution should not flow evenly, add a little water. The coating should, however, be of considerable thickness. Then dry—of course in the dark—and expose in the pressure frame under a *very* intense negative. The time of exposure will be rather less than for silver prints, and the image will appear of a dark brown on a yellow ground. In the photo-

* Continued from p. 588.

lithographic process the paper at this point is coated with printer's ink; but in the present case we require the print in some vitrifiable pigment and so must manufacture one for our purpose. A varnish used by lithographers for mixing with dry colours will serve our purpose for mixing with any of the previously enumerated metallic oxides so as to form a thick creamy paste with which to cover our paper by means of a dabber. Soaking in water and the application of slight friction will remove the compound from those portions which have not been acted on by light. We thus obtain a picture, in any pigment we please, in a form ready for the potter's hands. This method will not, however, give us half tone; but for copies of engravings, &c., we have not the slightest doubt it would be found to answer admirably.

Prints on paper can also be obtained in one or other of the numerous processes for printing in different metals which have been given from time to time. And here we have no difficulty on the question of half tone.

Some of the processes suggested by Mr. Burnett would no doubt answer for this purpose; of these perhaps the best is the chromatype. A paper is coated with bichromate of copper, and well washed after exposure to remove the sensitive material from the parts which have not been acted on by light, when an application of yellow prussiate of potash gives a red brown picture. Several other methods which, unfortunately, he has only roughly suggested, could no doubt be worked out. The bichromates afford an extensive scope for experiment.

An iron printing process that we published a few years back, would also enable us to obtain pictures that could be transferred to articles in earthenware. At this moment we have by us some of these prints so deeply toned with gold that they present quite a bronzed appearance. They were produced as follows:—

Paper was floated for about one minute on a sensitizing solution, composed of

Albumen	two parts	1 oz.
Water	one "	
Ammonio-citrate of iron ...	50 grains	
Bichromate of potash	saturation.	

Exposure under a negative, and subsequent washing in several changes of water, gave a yellow brown picture on a white ground. Rather a strong solution of chloride of gold, say two or three grains to the ounce, was next poured over the print, which, after being again well washed, was treated with a solution of gallic acid. The image now appeared composed of gallate of iron, with quite a thick deposit of gold. One of these prints we have just placed in dilute nitric acid to dissolve out the iron, and the result is that a strong image in gold remains. Another print, untoned with gold, placed in the acid at the same time is entirely discharged from the paper.

But we can tone the photograph with other metals beside gold. For instance, a solution of sulphate of copper applied instead of the gold, coats the image with a thick layer of that metal in a few seconds.

We feel assured that experiment in this direction will be well repaid.

A little careful manipulation will enable us to obtain these prints on glass. To this end, coat a glass plate with the sensitizing solution, and, after exposure, pour over it alcohol containing a very little acetic acid; or, perhaps better still, a strong solution of sulphate of iron. Wash, and proceed as before.

As to the colours to be got by the methods we have suggested above, although a reference to the process of enamelling given in the first portion of this article may be some guide, yet we should not like to speak with confidence thereon, until we have tried the test of experiment.

Generally speaking, there is less difficulty in producing the image for fixing than in actually burning it in. The readiest plan is to have a kind of dish of sheet-iron constructed. It should be three or four inches deep, with the bottom slightly rounded, so that the glass plate may touch at the ends only, and if it has a cover all the better, as the cooling can then be better regulated. In an apparatus of this kind a plate will soon be sufficiently heated over an ordinary fire.

But to produce the best results with any degree of certainty, it will be necessary to hand the prepared plate over to the glass manufacturer to be placed in a muffle and passed through the furnaces in the ordinary manner—a process which takes three or four days in its accomplishment. Some time back a friend offered us such a facility, but at that time experiments in another direction claimed our attention. Now, however, we may probably remind him of his offer, and place the results of our experiments before the readers of this journal.

Critical Notices.

THE PHOTOGRAPHIC NEWS ALMANAC; or, The Year-Book of Photography for 1862. London: Photographic News Office, Paternoster Row.

We cannot, for obvious reasons, enter into much critical examination of this work, nor, however highly we may think of it, can we, with any propriety, enter into commendation of its worth. We may, however, for the benefit of those of our readers who are interested in the matter, briefly state the character and contents of our Year-Book, and the aim we kept before us in compiling it.

An almanac is in its own nature always a book of constant, almost daily reference, and we have endeavoured in our Photographic Almanac to include, not only a calendar for the year, and all the usual information which constitutes almanacs generally useful, but have added everything we thought likely to be of service for constant reference in the photographer's daily practice. Members of societies will find their meetings duly indicated in the calendar opposite the date; whilst lists of officers, &c., are detailed on another page.

The Annals of Photography for 1861 contain an epitomized photographic history of the year up to the period of our going to press. We have given in a series of articles a careful digest and re-statement of the processes in everyday use, in which the formulæ and manipulations are based upon our own experience, and that of many of the best photographers of the day, with whom we have personal communication. These articles include the following subjects:—Iron Negatives: How to Produce them, and the Proper Conditions of Delicacy and Brilliancy. Modes of Developing; Intensifying Processes; On Printing, Toning, and Fixing; On Mounting Photographs; and Collodion Positives. A series of brief articles include Hints on Landscape, Marine, and Instantaneous Photography; on Portraiture, and on Album Portraiture; on Enlarging and Copying; and on the Solar Camera. A brief, but complete statement of the new and modified processes of the past year follow; and also a statement of formulæ and manipulations of the chief Dry Processes at present practised. Various useful tables, and other useful matter complete the work. How all this is done, we invite our readers to ascertain for themselves.

CROGER'S POCKET METRONOME. 483, Oxford Street.

We have received from Mr. Croger one of his convenient little pocket metronomes, or seconds apparatus. It is a very simple and convenient aid to marking time in the operating room, as a guide for exposure. Many operators are in the habit of counting the time: such a plan is very uncertain, as the state of health, or excitement, and a variety of other circumstances, will vary the rapidity of the counting. Some definite method should be adopted, and Mr. Croger's pendulum is one of the simplest and most certain that can be used.

THE LATE PRINCE CONSORT.

Although not strictly within the province of a scientific journal to refer to the late national bereavement in its national relation, we cannot avoid expressing our deep sense of the loss sustained by photography, in common with art and science generally, of which His Royal Highness, the late Prince, was such an active and constant patron. It is, perhaps, impossible to estimate his influence in the advancement of art culture throughout the kingdom during the last twenty years, and his most enduring monuments will be found in the various institutions for art education, which owe their existence, not only to his suggestions, but to his unvarying personal effort and fostering care. As most of our readers know, he had not only a high appreciation of their art, but a technical knowledge of its practice, and was directly connected with photographers generally as patron of the Photographic Society of London. We must forbear, however, in these pages from anything beyond expressing our deep sense, as photographers, as well as subjects, of this heavy national sorrow.

PANORAMIC PHOTOGRAPHY.

BY THOMAS ROSS.*

I have this evening the pleasure of laying before the Society a complete set of the apparatus necessary for the production of panoramic photographs 10 inches in length, and including an angle of upwards of 100 degrees.

The set of apparatus consists of a plate box for one dozen plates, a holder for the curved plates while being cleaned, a water-tight bath with dipper, a camera with lens and tripod-stand, and a printing-frame, all packed in a varnished pine case with handles, and secured with lock and key.

The plate box has slanting grooves suitable for plates of the required curve.

The holder for cleaning the plates consists of a flat base-board, surmounted by a curved board lined with cloth, to prevent the glasses from breaking or being scratched. At one end of the board is a fixed overlap of wood for the plate to rest against; at the other end is a hinged flap, which enables the manipulator to clamp the plate safely and securely whilst it is being cleaned.

The bath, which is made of gutta-percha, is curved rather less than the plates for which it is required, to prevent the collodion film from being injured during immersion. The bath is rendered water-tight by means of wooden top lined with india-rubber, firmly compressed to it by three brass clamps. There are occasioual objectors to the use of gutta-percha baths; but, in order to meet the wishes of these objectors, I am in treaty with a manufacturer for the production of curved glass baths; these will, of necessity, be more costly and more weighty than gutta-percha ones, to the latter of which I must confess I see no objection when they are made of pure material.

The plate-dipper, which has the form of an enlongated horseshoe slightly hooked at the extremities, is made of strong metal wire, thickly coated with gutta percha. A dipper made of pure silver, or of brass wire thickly electro-plated, might be employed if preferred.

The stand is the usual folding tripod, with triangular brass top, to which the camera is fixed by a bolt passed through the camera and clamped under the triangle.

The printing-frame differs from ordinary frames in its being curved, and in its having inner shoulders thickly lined with india-rubber upon which the negative plate rests. The back-board, which is hinged in the middle, presses three or four thicknesses of soft pliant flannel against the excited paper, and is kept in position by two strong springs in cross bars, hinged at one end and hasped at the other. With this as with the flat frame, the operator may with the greatest facility examine the progress of the print without the least danger of displacement.

The camera and lens require a more minute description, which will now be given in detail.

The camera has a sliding body, which is adjusted by a screw motion at the back, and secured in adjustment by a clamping screw on the top of the camera. As it is important to place the camera parallel to the plane of the horizon, two spirit-levels, placed at right angles, are fixed in the top of the camera: by this arrangement the camera may be placed in a proper position with more facility. The camera has a sliding front, to which is attached a square box with a hinged shutter fitted with a clamping screw. This shutter, which acts as a cover to the lens, may be used both for instantaneous photography and for regulating the amount of exposure required by different parts of the subject: it acts as a shield to the upper portion of the lens, and may be made to obstruct the rays from the sky, thus enabling the operator to produce fine effective clouds on a sufficiently exposed plate. It is scarcely necessary to state, that both the plate-holder and the ground focussing-screen have the exact horizontal curve of the field of the lens.

I now come to the description of the lens, which is unquestionably the most remarkable part of the apparatus; and I think I cannot do better than quote the words of the inventor, Mr. Sutton, as contained in that portion of his specification which relates to the form of lens which I have the honour of exhibiting this evening.

"My invention relates to the construction of a compound achromatic lens for taking photographic pictures wherein au unusually wide angle of view or extent of field is to be included. The compound lens is composed of two single, thick, concavo-convex lenses made of glass, the curved surfaces of which are portions of concentric spheres. They are secured to a suitable mount in such a manner and position that the curved surfaces of both of them (that is to say, all the four curved surfaces) are concentric, their common centre being a point in the axis of the compound lens, and the lenses having their concave surfaces opposite to each other. In the space or cavity between the concavo-convex lenses is contained a transparent fluid of lower refractive and dispersive power than the glass of which the lenses are made. Water is a suitable and convenient fluid to employ. By assigning proper radii to the surfaces of the glass lenses, the compound lens is rendered achromatic and convex, so as to produce real images of objects. The two glass lenses may be made of the same kind of glass, and equal in all respects, but that is not a necessary condition. By using lenses made of different kinds of glass, and giving their concentric surfaces suitable radii computed according to known principles of optics, the compound lens can be made achromatic, and at the same time its spherical aberration can be reduced. The compound lens is provided with a central diaphragm, having a central circular aperture of suitable size in order to give sharp definition when objects at different distances from the lens are included in the view. This diaphragm is placed between the lenses and within the fluid in such a position that the centre of its circular aperture is at the commou centre of the spherical surfaces of the lenses."

The description of the diaphragm (so very insufficient in the specification) I shall give from Mr. Sutton's paper read at the last meetiug of the British Association, held at Manchester in September last:—

"The central diaphragm is another curious part of this instrument. It is evident that, if it were merely furnished with a central circular hole, the sides of the picture would

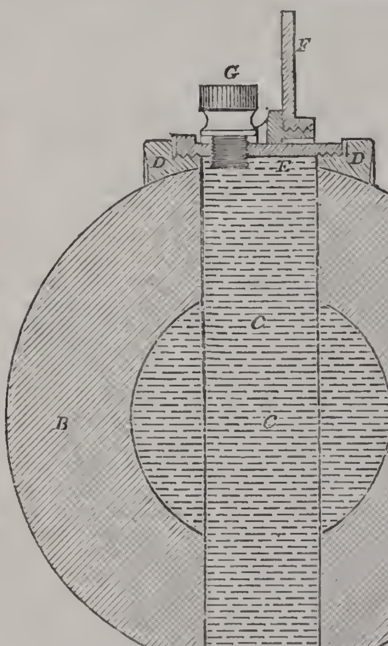
* Read at a Meeting of the Photographic Society, on the evening of Tuesday, December 3rd, 1861.

be less illuminated than the centre. To meet this inconvenience I have made the central hole elliptical, and have placed in front of it two upright thin partitions, radiating from the centre, and looking like the open wings of a butterfly. These stop some of the light of the central pencil, and make it cylindrical, and at the same time they make the side pencils cylindrical also, and of the same diameter as the central one. This simple contrivance answers perfectly in equalizing the illumination."

I now turn again to the specification; but may here remark, that although the lens before you is substantially the same as that described by Mr. Sutton, it somewhat differs from it in this respect, that the mounting has been improved and simplified. Mr. Sutton, describing the lens with its original mounting (a sectional diagram of which you have before you), continues in his specification :—

"Fig. 1 represents a vertical section of the simplest form (by-the-bye the best form) of panoramic lens and amount wherein the glass lenses, A, B, are both alike in all respects, and made of the same kind of glass. When this construction is adopted and the internal cavity C is filled with water, the lens will work with sufficient accuracy for most practical purposes, if the following dimensions are employed, viz., if the lenses are both composed of the same light flint glass, their inner radii may be one-half the length of their outer radii; if they be made of the same colourless crown or plate glass, their inner radii may be two-fifths of their outer radii.

"I do not confine myself to any particular form of mount, but the one shown in fig. 1 will be found to answer well in practice. According to this form of mount, each lens is fitted into a metal ring D, provided with an external screw-



thread for the purpose of screwing them fluid-tight into the intermediate ring or zone E, provided for that purpose, with internal screw-threads at each end. This zone E slides freely within the boss of the flange F, by which the entire lens is secured to the woodwork of the camera, the sliding motion serving to facilitate the adjustment of the focus. The cavity C between the lenses A, B, is filled with water, or other suitable fluid, the ring E being provided for that purpose with stoppered inlet and outlet apertures at G and H."

I will now take leave of the specification, and observe that, as the camera has sufficient screw-adjustment, a sliding adjustment to the lens became unnecessary, and has therefore been dispensed with. The stoppered apertures at G and H have also been done away with as unnecessary for filling the lens with water, which operation may easily be effected in the following manner :—

Unscrew the front component of the lens, then pour perfectly clear water into the reservoir till the water reaches the brim, and slightly agitate the water to expel the air, then screw on the front lens. The small bubble of enclosed air which has not been got rid of will rise much above the spherical concavity of the lens, and thus become of no consequence. The brass mounting is made with so much accuracy that the lens, when screwed up, is perfectly water-tight.

Some persons have supposed a certain amount of difficulty to exist in coating curved plates with collodion. There is, however, no real difficulty in the matter. If Mr. Collis will be good enough to coat before the Society a few of the curved plates I have brought with me, he will be able to show you with what facility the operation may be accomplished; and if any of the members present will try the experiment, they will find it exceedingly easy.

I beg to say, in conclusion, that I shall now have the pleasure of submitting to your inspection the first panoramic negatives taken by Mr. Harral, in order that you may judge what amount of success a first attempt may meet with.

I must apologize for again introducing some prints which have already appeared before you; but as there may be some members present who were not here at the last meeting, it may afford them some gratification this evening to obtain a sight of panoramic prints.

Those who may be further interested in this matter will find it completely discussed in the article "Optics," in the *Photographic Quarterly Review*, for June, 1860, and also in the *Photographic Notes*, of November 15, 1861, in a paper by Mr. Sutton read at the Newcastle Photographic Society.

THE NEW PICTURE GALLERIES.*

When that estimable but misguided martyr to principle, Mr. Samuel Pickwick, refused to pay the sum which the jury had awarded to the widow, and the costs of her advocates, Messrs. Dodson & Fogg, and chose that satisfaction should be given to those tormentors upon his body rather than upon his purse, the first torture he underwent in the Fleet was a characteristic one. He had to sit for his portrait. He found himself the centre of a crowd of turnkeys and jail officials, whose business it was to look him over and stare at him until they should be absolutely certain of knowing him again when present, or being able to describe him if absent. It is needless to say that the same childlike innocence and natural imperturbability which had supported the great philanthropist in other critical periods of his career—in the Village Pound, in the Justice's Hall, and in the lady's bedroom at Ipswich—enabled him to endure the consummate and final misery of sitting for his portrait in the Fleet. But the story of his endurance, as narrated by his great biographer, Mr. Dickens, we recommend to the perusal of those unhappy men who, in the present day, are perpetually being pestered and forced to have their portraits taken.

An elegantly bound album, containing some thirty or forty so-called "likenesses," has become one of the indispensable ornaments of every lady's table. Be it so: the books are pretty, though their contents may not be; and we should acquiesce in the existence of these as we acquiesce in any other fact accomplished by the despot fashion, were it not that the owners of these books are continually pressing upon us the necessity of sitting for our portrait, in order that our person, distorted by the painful process of photography, may be enshrined by the side of other victims to this rage for *cartes de visite*.

A gentleman has, perhaps, escaped for some time the effects of this epidemic, and has been exempted from the general per-

* From the *London Review*. See article on another page, "Photography and Contemporary Literature."

secution. His acquaintance, the owner of the miniature picture gallery, has apparently forgotten him, or he begins to hope that he is not considered sufficiently intimate, or presentable enough to receive a summons to that mimic court. But he is deceiving himself. The owner of the book has been busy hunting up country relations, old friends, and the rest of the elect who are to occupy the first half of the volume; and now that the tale is complete his turn is come. He has lived in freedom so far, only because he could at any moment be arrested and sent off to the executioner. He has gone loose on sufferance like a sacred ichneumon in Egypt, or a Frenchman under the *Lois des suspects:* and at last his time arrives. He is handed over to the tender mercies of Maull, and his co-operator Polyblank; or Silvy does his silent office upon him. He is seized and photographed in a trice.

Which of us is so fortunate as not to be able to recall sufferings in the Inferno of some eminent photographers? to recollect how, while waiting our turn to pass into the dusky abodes beyond, we surveyed, in all the misery of protracted anticipation, the shadowy forms of those who had before passed under the operation; searching, like bereaved relatives in a Morgue, for the disfigured appearance of a friend. We had no difficulty in recognizing one when found. Hideous as he may have seemed, the operator had left him enough of his former self to enable us to appreciate and lament the change. Like Æneas we recognize our Hector—

> "And weep to see the visionary man;"

or, like him, we mourn over our Deiphobus—

> "Whose face and limbs are one continuous wound.
> Dishonest with lopped arms the youth appears,
> Spoiled of his nose, and shortened of his ears."

A photographic likeness cannot be true, as will appear from the consideration that it is the result of one momentary isolated impression, and not a careful generalization. If a person who had only known us for one day were to undertake to draw our character, the odds are as Lombard-street to a China orange, that he grossly misrepresents us. Or, again, if he were to describe the our person, dwelling almost entirely on one feature, or one attitude or habit, we should complain of being caricature. And this is the inherent fault of which we accuse photography; it caricatures.

A good portrait-painter studies carefully the subject of his picture, endeavours to live awhile in his company, draws him into frequent and free conversation, marks his habits and looks under various circumstances, gathers up all the particulars of his individual appearances, and then unites and combines them in one great general resemblance. It is true, indeed, that some painters are prone to over-generalization. It does not do to refine away all excrescences until you get a perfectly smooth and polished surface, because by this process character and truth will be as much sacrificed as in the instantaneous impressions of photography. But it is only when generalization passes into idealism that this evil can occur; whereas the impressions of photography, like all first and sudden impressions, are always only half-truths. A "pistolgram," as these rapid portraitures are now (especially when the subject is an infant) designated by the faculty, is taken, the subject is flashed upon paper, a momentary appearance is produced, and the result is invariably more or less a caricature. This view is borne out by the fact that the photographs of men are generally much more tolerable than those of women. Men with their hard outlines, decided carriage, and natural lack of gracefulness, are better subjects for offhand portraiture than women. There is nothing decided about a charming woman. She is, in appearance, what Sir Walter affirms she is in character—

> "Variable as the shade
> By the light quivering aspen made;"

and how can photographers hope to give any imitation of the subdued and softened qualities which Nature has so artfully fused, so skilfully combined in her? Her outward visible form requires just as much study to be appreciated as her inward graces; and this study is just what the photographer cannot give her. We wonder what Wordsworth would have thought of one of these modern representations of his "phantom of delight," or Coleridge of his Genevieve? and then to see the portraits of these fair creatures on a hundred drawing-room tables, or in a dozen shops, as common and as vulgar as clowns at a Bartlemy Fair! Almost all have a cast in the eye. Others have either an unmeaning grin, or a silly smile, or a surly frown that Timon of Athens might have envied. One young lady looks saucy, another as melancholy as Mariana in the moated grange, another has such a dangerous look that Petruchio himself would not dare to marry her. With these defects in themselves, the figures stand or sit in the centre of a perfect chaos. Panels of walls, doors, jars of conservatory flowers, tables, and other articles of furniture, lean, roll, and tumble about the apartment, as if spirit-rapping was going on, in every position out of the perpendicular. The central figure may be in focus and straight, but if even she escape with no distortion, such as a monster hand or foot, or a cheek that seems afflicted with the mumps, all her *entourage* is reeling around her, as if she had been taken in the saloon of the big ship during the great storm.

Women are, as we have said, the chief sufferers from this pictorial misrepresentation. But we cannot pity them. They are also the chief maintainers of this, as of every other troublesome fashion. We have no doubt a woman would rather be represented by a good oil-painting, but, failing that, she offers herself to the photographer. Most women would rather endure any misrepresentation than no representation at all; just as they would rather see their faces in a broken glass than in nothing. Like Narcissus, the fair one is injured by love of her own form, and then naturally enough wishes to inflict the same fate on others. A photograph book is given her by some gentleman in exchange for her likeness, which has just been taken by Silvy or Southwell. This may be multiplied to any extent, and every man who is in the original owner's set at Trinity or Christ Church may be favoured with a copy.

Women are not, therefore, to be pitied. If it pleases them to be so bandied about, it cannot hurt us who are of the vulgar sex. Only let them leave those in peace who object to their distorted limbs becoming public property, and cease to force into the photographers' studies men who, like Plato's philosopher, seek to pass through life in honest and safe obscurity.

Proceedings of Societies.

South London Photographic Society.

The ordinary monthly meeting of this society was held in St. Peter's Schoolroom, Walworth Road, on the evening of Thursday, December 12th, Mr. Sebastian Davis in the chair.

Mr. G. Wharton Simpson handed to the society a series of fine photographs of Hereford Cathedral, and other subjects, which were presented by Mr. Warner, of Ross, one of the provincial members of the society. He also presented from the proprietors of the Photographic News a copy of their almanac for the coming year. The thanks of the Society having been recorded for these gifts,

Mr. Wall Honorary Secretary then said: since our last meeting, the committee which our recent memorial to the commissioners suggested, has been appointed; and consists of Mr. Peter Le Neve Foster, the Earl of Caithness, Mr. Kater, and Dr. Diamond. With regard to the first-named, doubtless very able and energetic gentleman, it is hardly to be hoped that with so many other branches of the department entrusted to his care, occupying his time and attention, that he will have much of either to spare for photography. With reference to the Earl of Caithness, I remember an excellent letter in one of our photographic journals, I think the News, in which a writer, signing himself "Progress" asked the reason why this same nobleman should be entrusted with a share in the management of the Photographic Society of London, inasmuch as he (Progress) had never heard of any one thing the Earl had done expressive of any peculiar aptitude for such a position, or of any particular interest he (the Earl) had ever evinced in the advancement of "the art and science of photography." Now the Earl of Caithness may perhaps have done good work for the art *in secret*, but although *he* might blush to find it fame, I think it is *now* high time, when he fills a position so vitally important to the interests and welfare of English photography, that *we* should all demand to know something about it, as otherwise we might be unfortunate enough to suspect that there was a greater love of aristocratic fellowship than photographic welfare, and more respect for big names than great duties, in this possibly very worthy and highly intelligent nobleman's appointment. It really makes me, personally, quite feverish to see such great interests trifled with, so imprudently, while those so seriously concerned stand idly and supinely by. From all quarters, and in almost every section of the press, daily, weekly, monthly, and quarterly stray fears have recently either found definite utterance, or dim foreshadowings with regard to the position which English photography, will occupy when contrasted with its foreign rivals. Now were photographers only true to themselves and to their art, we should have nothing to fear, we have in this country, I confidently believe, some of the best photographers in the world, I say it fearlessly, but John Bull always had, from the earliest times, a strange prejudice in favour of foreign artists, and never did believe very firmly in prophets of native growth. As an instance of which, I might point to a paragraph in the *Daily Telegraph* respecting a fabulously valuable lens used by a famous French photographer, the possession of which being due to government aid, gave him advantages which no English operator could command. Knowing all about these matters we may laugh at this, but there is in it much matter for serious consideration. Such things show the way that wind blows, which may, if the interests of the art be not sufficiently cared for next year, carry away the patronage to which it owes both its present position and future prospects.

Perhaps I may be permitted to ask why "the Parent Society," to use a term now generally adopted, although confessedly inappropriate, (inasmuch as no other society was ever, I believe, indebted to it, in any single case, either for existence, assistance, or encouragement), why the Parent Society, having so resolutely pledged itself to render Her Majesty's Commissioners *no assistance*, have at the eleventh hour suffered four of its chief officers to undertake the very duties it so resolutely, not to say obstinately, declined accepting. What is there to justify this odd change in the society's intentions? Dr. Diamond informs us that when he was requested to act as one of the committee in question, he consulted—not the council and officers—but the president of the society "as to how he should act," and that the Lord Chief Baron said "he thought it was desirable, now that the society had made their protest against what they conceived was an improper classification—that *they should aid the Exhibition to the best of their ability*." This is doing at *last* the very thing this society suggested doing at *first*. But what remains to account for the waste of so much invaluable time? Could not the Parent Society have done under protest last May what it is now doing with such ill grace in December? or was it absolutely necessary to prove how actively (?) this so-called Parent Society undertakes the duties of its position, and how wisely (?) it uses the power and influence entrusted to it by photographers, that nearly seven months should elapse between making the protest and adopting a judicious course of action. In Paris we are informed the Imperial Commission proceeds rapidly "in planning out its portion of the Exhibition," and that exhibitors are being "brushed up in various ways," and urged to "make up for lost time." We hear, too, that preliminary exhibitions are already organized, in which the various objects "will be arranged in the same manner as they are to be seen eventually in London," and that "the Educational and Photographic Exhibitions are also proceeding."* Are we as active and energetic here?

It may be remembered by many how, before the Exhibition of 1851, great difficulties were experienced by the local secretaries of the various sub-committees, in inducing exhibitors to send in their goods promptly enough, and it was stated in the daily papers that in many cases the favourable aspect of various departments was *entirely* due to these "energetic agents," who had "brushed up in various ways"† the neglectful or procrastinating, but more valuable exhibitors. Who will undertake these duties for photography? Would it not be wise to entrust such to the officers of the various provincial photographic societies, as gentlemen best acquainted with the resources of their own immediate neighbourhoods in the way of works calculated to do credit to British photography, or is this also to be left to chance and accident, by which so much mischief has been already effected.

But having opened this subject, and called attention to one or two of the points which I think important. I surrender its further consideration into your hands. I have spoken out boldly, but honestly in the interests of an art to which, in connection with this society, and through other channels I have devoted a comparatively large portion of ill-spared time and labour.

One of the great French poets said, "No gentleman should neglect duties imposed by an honour which he had solicited," and every member of this society associates himself, when soliciting election as a member, with the mission for which only it was organized, viz., "the advancement of photographic art and science." I, therefore, shall not apologise for introducing these few remarks, or for placing before you their subject matter.

It is very possible that I may be both misunderstood and misrepresented, but I must risk all that, and I am content to do so. We wanted to manage our photographic affairs, next year, in connection with the International Exhibition, active, energetic, *amateur* members of our photographic societies; selected, not from their social position, or their elevated rank, but from their extended knowledge, both of the art, and its professors, that while competent to systematize, select, and arrange, they might also so judiciously allot the space at their disposal, and choose from those most competent to fill it worthily, that the result would be at one and the same time, honourable to the country, favourable to the art, and most profitable to its professors as representatives of a rapidly increasing branch of national industry and art.

The Chairman observed that it must be highly satisfactory to photographers at large that the committee had been appointed, and pre-eminently so to them as a society, as they had been the first to give a practical aspect to the question, by making the suggestion which had been adopted by the Commissioners. It was scarcely so satisfactory as might have been desired in one point; he referred to the duties being entrusted to so small a number of persons. He had hoped to have seen a committee appointed, consisting of gentlemen from all parts of the country. Regarding the allusions which had been made to the action of the society in the matter, they had not been at all anxious to take individual action in the matter; their aim had simply been to impress upon those in power that the subject was one which should not be trifled with. The credit of English photography was at stake, and with that our artistic capacities as a nation, and our reputation as scientific investigators. Photography, it had been felt, was, in the land of Talbot and Archer, peculiarly a national matter; and it became us to prove, if possible, that we were as active and capable in carrying out the practical applications of the art as we had been in discovery and theory. He trusted that the committee would not be left with the few names already published, but that more would be added, so as to give confidence to photographers throughout the kingdom. He hoped we should in the coming Exhibition, show to the world at large that English photographers regarded science and art as twin sisters, who were indissolubly united in this most attractive discovery of the last half century.

Mr. Valentine Blanchard then read a paper intended for the first meeting of the present session, but delayed, entitled "A Prologue for the Season." (See p. 592.)

Mr. Wall intimated his conviction that the educational element, in the shape of classes for chemistry, &c., scarcely came within the scope of the society, and would prove very expensive. Regarding the Experimental Committee, Mr. Blanchard had apparently overlooked the fact that three reports presented to the society last year, were the results of very many meetings. As to composing such a committee of the whole society, it already included the names of all who were able and willing to help, and of more than had done so.

Mr. Martin suggested, as a means of giving increased ease and geniality to the meetings, that the formality of rising to address the chairman and meeting, should be dispensed with. Many gentlemen might be able to offer useful suggestions, or make important remarks, who did not feel at ease to rise to do so.

Mr. Wall did not approve of the colloquial character this practice would give to the meetings.

After some further conversation on this subject, in which Messrs. Simpson, Howard, Wall, Martin, Blanchard, and the chairman took part, it was resolved that in future members should be at liberty to address the meeting without formally rising to do so.

Mr. Blanchard in replying to Mr. Wall, urged the importance of his suggestion regarding classes; he thought it would be possible to form a chemical class, which should be self-supporting, at a small expense to the members, and no trouble to the society, and the advantages of which it would be impossible to over estimate.

The meeting was then made special, to consider the propriety of securing a more central place of meeting, which should be more convenient for members and more in accordance with the

* *Illustrated London News*, 1851. † *Daily Telegraph*.

advancement and wide-spread influence of the society. After some discussion, in which the importance was urged of making no change which would be inimical to retaining the name "South London Society," to which the prestige of activity and energy attached, it was resolved to adjourn the question for the consideration of another meeting, the committee in the meantime undertaking to make enquiries and report on the subject.

Correspondence.

PHOTOGRAPHY IN GERMANY.

Elberfeld, December 12th, 1861.

Professor Roux, of Cassel, communicates in the *Photographisches Archiv* his experience with the solar camera. He has made a large camera, of 9 feet length and 4 feet high, upon wheels, of dry wood, and painted with oil colours; all can be so arranged in it, that neither the condenser, the negative, the objective, nor the paper frame can be changed in position. It is so guarded against the sun rays by large screens covered with linen, that only the reflector is exposed to the sun. Nevertheless the wood is very apt to warp. It is so arranged that the operator enters with half his body into the camera, and moves with the aid of a slider to the objective as well as to the frame. The mirror is turned from outside.

In such a small room, the heat is often so high that the paper becomes dry, and loses its sensitiveness, so that it needs several hours to take an impression. For this reason the author wets the frame to which the paper is fastened every five minutes, to render the paper sensitive. The paper should be strongly salted and sensitized in a strong nitrate bath for this purpose.

Some time ago, a photographer of Aix-la-Chapelle advertised in the journals a new invention; "Photographs without silver and gold, hyposulphite, carbon, nitrate of uranium, &c. &c." This advertisement produced great excitement amongst photographers beyond Germany and France. Some persons asked the price of the secret. It was very cheap indeed! only 50,000 francs for one country. The inventor does not yet make use of his own wonderful invention, but sticks yet to old hypo. But now comes the best. Some doctors have examined the specimens he has made of his new method, and find this is only an old and well known one, viz., gallate of iron—a process published in all photographic journals.

I may mention on this occasion that I obtained remarkable good results with a paper prepared after Mr. Hannaford's formula. The prints are only too vigorous, the half-shades are absent; when using thin negatives the prints become too weak, but I should think this process would give sufficient results when modified.

Recently I visited the *atelier* of one of our most celebrated photographers, M. Hanfstängl, in Munic. His photographic re-productions of lithographs after the original paintings of the Dresden Gallery, form a beautiful and very interesting album of 120 leaves. Among the best copies are—"The Foundling, Moses," by Paul Veronese; "Madonna," by Murillo; "Charles I.," by Vandyke; a "Dutch Inn," by Ostade; "Venus," by Guido; "Satyrs and Nymphs," by P. P. Rubens; "Potiphar's Wife," by Cignani; "The Nuptial of Cana," by Paul Veronese; "St. Sebastian," by Correggio. The copies are printed upon arrowroot paper; they have a very agreeable and rich sepia tone.

The *atelier* of M. Josef Albert, of Munic, is perhaps the greatest in Germany for re-productions of works of art. The copies of Kaulbach's cartoons are too well known, also in England, to be mentioned here. The most recently published collections are Kaulbach's "Shakspeare Album," and his "Death of Julius Cæsar."

In this year several books have been published with photographic illustrations. An edition of Schiller's Poems, and an illustrated Family Bible being the most important ones. Photographic book illustration will only come into general use when a good carbon process will be perfected. With respect to this process, I can communicate an encouraging fact.

You know M. Poitevin, of Paris, has patented for France a new process for producing carbon prints. Several persons have got licenses from him; also a painter, M. Joly Grangedor. This gentleman has now an *atelier* for copying after this process. When I visited him recently at Paris, I found several artists occupied with very large productions, and I saw a large quantity of prints which were without fault, and which could not be easily distinguished from chloride of silver prints. They were chiefly copies after plaster busts. The delicacy at half-tones was incomparable in several figures.

The microscopic photographs mounted in rings, watch-keys, scissors, and knives, come every day more into fashion in France as well as in Germany. M. Dagron, of Paris, has patented this *genré*, and has had a process with some other photographers about this subject.

At Brussels I saw some life-size photographs at Ghemar's *atelier*; the execution was not bad, only they were too much touched up.

An operator communicates me the results of some experiments about the strength of an iron developer. He used a collodion composed of—

Alcohol	1 ounce
Ether	1 „
Pyroxyline	10 grains.

Iodized with the following solution:—

Iodide of lithium	10 grains
„ cadmium	5 „
Bromide potassium...	5 „
Alcohol	1 ounce.

Nitrate bath, 1 oz. nitrate of silver to 12 oz. of water, saturated with iodide of silver.

A saturated solution of sulphate of iron had been so diluted that 1 ounce of the liquid contained 2 drams of the salt. A sensitized plate exposed twenty-five seconds to the light of a candle, and developed by that solution, gave immediately a very dense image, without the trace of a spot at the place where the developer had been poured upon the plate. Then the strength of the iron solution was so changed that the following proportions were obtained:—1·6, 1·8, 1·16, 1·32, 1·64, 1·72, 1·124. With these solutions he developed seven proofs. The results were as follows:—

No. 1.—1 drm. sulphate of iron, 6 drms. water. Density, vigorous and black.

No. 2.—1 drm. sulphate of iron, 8 drms. water. Density, good brown.

No. 3.—1 drm. sulphate of iron, 16 drms. water. Density, good, a little less vigorous.

No. 4.—1 drm. sulphate of iron, 32 drms. water. Density, feeble, bluish.

No. 5.—1 drm. sulphate of iron, 64 drms. water. Density, feeble, transparent.

No. 6.—1 drm. sulphate of iron, 72 drms. water. Density, feeble, too vitreous.

No. 7.—1 drm. sulphate of iron, 124 drms. water. Density, very feeble.

The first numbers did not show a spot; where the developer had been poured, this spot appeared the more marked, the more diluted the solution was. After the fixation the first numbers possessed a gray, dim surface, the last ones on the contrary had a fine white aspect, and became very brilliant; No. 7, showed the purest metallic lustre.

When a plate had been exposed fifteen seconds in the camera, in a glass room, one half of it was coated with the developer No. 7; after two minutes only the traces of a proof became visible; then the other half was coated with the first solution, and immediately a fine negative developed under its action. One part of acetic acid was always added to 4 parts of sulphate of iron. As the best developer for negative, the operator recommends: two ounces sulphate of iron, half an ounce of acetic acid, eight ounces distilled water.

Paul E. Liesegang.

Photographic Notes and Queries.

TONING BATH.

SIR,—Please correct a mistake you have made in the toning bath I sent you, which appeared in last week's NEWS. Read—

Chloride of gold ... ... 1½ grains
Sodæ acetate ... ... 2 drachms.

By altering this you will oblige A CURE.

Talk in the Studio.

PHOTOGRAPHY AND THE PAPAL GOVERNMENT.—The paternal Government of the Vatican has just issued two edicts of rather a peculiar description. One, which forbids tailors, tailoresses, and milliners to work on fête days, and the keepers of "ristoranti" and eating-houses to serve any food except that of the most "maigre" kind on those holy days. To appreciate the inconvenience of this despotic order, it must be remembered that for the next six months there will be on an average two of these fasts out of each week, besides the "muckle fast they ca' Sunday." The second order relates to the art of "photography," and so great are the pains to suppress this useful science, and so lengthy the clauses of the police regulations on the subject, that the "New Zealander" (supposing him to have come to Rome to try his prentice hand on the Coliseum) might well suppose it to be the "black art" itself. While the police is occupied in this moral and religious work, robbery is rampant and murder of daily occurrence. Between the 10th and 20th of last month there were seven cases of stabbing in the streets of Rome. But perhaps if the police had prevented these crimes, or traced out the authors of them, religion might in the mean time have been scandalised by a tailor gaining five paul, and therefore dining off meat on a fast day, and decency outraged by the display in a shop window of a photograph of the Venus of the Capitol, or the Apollo Belvidere.—*Daily Telegraph.*

CORONATION PHOTOGRAPHS.—The *Times* says:—Messrs. L. Haasse and Co., of Berlin, Photographers to the Court, were honoured at the time of the recent coronation of the King of Prussia, with sittings from the Imperial and Royal guests, ambassadors, and other personages of high note present at the ceremony. These coronation photographs consist of five groups, divided into nationalities, the leading representative of each nation being a distinct group of his own. Thus there is a group of his Imperial Highness the Grand Duke of Russia and ten persons, another of Lord Clarendon and nine personages, another of the Duke of Magenta and suite, &c. The series form an interesting momento of the coronation. There are two series, one on a large scale to form an album, the other in the *carte-de-visite* form. The latter, which we have seen, do great credit to Messrs. Haase and Co.

THE FATE OF HEROES.—Mr. Russell, the *Times* correspondent, says:—Captain Wilkes is, as I said he would be—and, indeed, not a shred of the prophetical mantle was needed to inspire the prediction—a hero at once, and the photographers are upon him!

To Correspondents.

F. F.—The best material for a dark tent is black "twill," lined with yellow material of the same kind. The number of thicknesses required will depend on the closeness of the texture and consequent power to keep out light. 2. An ordinary plate box will answer very well, but one of zinc would be less liable to warp from moisture. 3. The question of fixing in the field, or at home, is purely one of convenience. If you have plenty of time, and a supply of water at hand, it is as well to fix at once. If not it is best to do it at home. We shall have pleasure in answering you any further specific questions, but can scarcely enter into general advice in this column.

O. B.—The mode described in the PHOTOGRAPHIC NEWS ALMANAC, in the article on "Copying and Enlarging," is the simplest for producing transparencies. The disadvantage of printing them by super-position is that dry plates must be used, and that the negatives rapidly wear out. If you print by super-position, a few seconds exposure will be sufficient, If you use camera-printing wet collodion may be used, or dry, just as may suit your general practice. The tone of the prints will of course be much affected by the process used. Tannin plates give as rich a tone as any we know. Your rapid stereo lens will answer very well for enlarging according to the method described in the ALMANAC, and you may enlarge from 2¾ inches to 6 or 8 inches, without serious loss. We have not seen any of the transparencies you name, but think it probable, from your description, they may be produced on tannin plates. Several articles on transparencies have appeared in the present volume of the PHOTOGRAPHIC NEWS, two of which, on May 3 and 10, were by Mr. S. Fry, who has had much experience in producing transparencies.

C. P. CHAPPLE.—The rolling machine of Bury Brothers, regarding which you enquire, is, as far as we have seen, a very excellent one, and much superior for rolling photographs to a lithographic press.

OLIVER OAKWOOD.—We cannot say with certainty the cause of the stains in your print. They appear to be caused by some trace of hypo left in the paper, and decomposed by contact with an acid. The print otherwise is pretty good, but slightly bordering on hardness.

A CONSTANT READER is thanked. The matter shall receive our attention.

W. G. G.—You will find an article on "Glass Houses" on p. 73 of our third volume. We should recommend you to increase your dimensions, if you can conveniently, to at least 24 feet long, and 12 or 15 feet wide. The space without glass at the back ground end may be about 5 feet. For the rest have as much glass as you conveniently can, and shut it off by means of blinds when not required. The amount of slope or pitch is a question for the builder, but be sure you have sufficient to throw off the water rapidly, and thus keep water-tight. Regarding the best lens for carte de visite portraits, that made at the last house you mention has produced the best work we have seen.

N.—We have not seen the glass for marking seconds, which you describe. It would doubtless be useless. We are obliged by your offer to send one for our inspection, which will enable us to describe it.

H. R. NICHOLS.—We are obliged by your communication, which shall receive early attention.

J. F. WARD.—Thank you for your prompt response to our wishes. We shall make use of your letter in an early number.

TIT TAT TO.—The edition of "Hardwich's Manual" from which you quote, is probably an old one, as the matter is not so stated in the 6th edition. Not having the old edition at hand to which you refer, we cannot explain. with certainty, the passage. Where the general term "excess" of anything is used, without statement of quantities, it is manifest that the amount is unimportant, and must be left to the judgment of the manipulator. In the same way you must use your own common sense as to what the author meant by "largely." In the circumstances named, adding six ounces of water to one of the acid solution would be diluting "largely." In like manner, it is unimportant how much water you have in the iron solution, so long as you have six parts of iron to one of gold. It is by no means certain that all the trouble for purifying the gold is necessary for toning purposes. A water bath is a double vessel; the lower part of which contains water, and so renders it impossible to apply a greater heat to the upper portion than that of boiling water. In making chloride of gold for your own use, it is not necessary to crystallize it; as it is quite easy to keep in solution. You will find a very simple method of making it given on p. 86 of our third volume.

W. D. B.—We cannot refer to you any especial information on the subject of copying engravings, &c. An old and intense collodion generally gives the best results for copying engravings; but for drawings possessing colour, a good bromo-iodized collodion answers best. The kind of negatives must depend entirely upon the subject. Line engravings are well rendered by intense negatives; but mezzotints and drawings require a fair proportion of softness. We are obliged by your kind wishes.

RHO DELTA.—We do not see any especial advantages in the lenses you mention; but we have not worked with them ourselves. Thank you for seasonable compliments.

G. L.—The glass forwarded will answer for a large room admirably. It cuts off all the blue and the greater part of the green rays.

PHOTOGRAPH.—We presume of all Mr. Greenwood's agents. 2. The PHOTOGRAPHIC NEWS, which is weekly; the *British Journal* and the *Notes* are fortnightly, and the *Society's Journal* monthly. 3. We cannot say, the sizes vary; and it has never occurred to us to compare them from time to time. 4. Mr. Croger's metronome is used by photographers for counting time in relation to exposure.

THOMAS CUMBERFORD.—We are a little puzzled as to what information you require of us, as your questions and statements are somewhat oddly mixed. A plano-convex achromatic lens will answer for producing landscapes, but is not suited to portraiture. Your tube of 11 inches long must be cut to about the same length as the diameter of the lens, otherwise it would cut off part of the image and limit your field. A lens of 10 inches focus is scarcely well suited for stereoscopic pictures. If you require further information, please state your questions definitely, and each one distinctly.

J. T.—We shall have pleasure in giving you the information you ask when you call upon us. We are always at the office on a Thursday afternoon.

JOHN HAWKE.—The album portraits sent are amongst the best we have seen. The single figure of the lady is very perfect throughout, and an exquisite specimen of definition. The group is well posed, arranged, and lighted, but the lens is unequal to the work. You will of course adhere to the lens of the English maker now. The vignette is one of the most charming little things we have met with. It has but one fault, and that arises from one foot being imperfect, either from faulty definition, or an error in vignetting. The pose, lighting, and composition, are good. The tones of all are rich and pleasing. We shall have pleasure in accepting your offer of further specimens, and of hearing more about them.

THOMAS WARDELL.—It is somewhat difficult to determine the cause of the streaks you name, if, as you say, you have taken every precaution to remove the usual causes; we can only recommend a more careful performance of the same acts as a remedy. As palliative measures, take care to have the film well set before immersion of the plate; always see that all floating scum is removed from the surface of the bath; move the plate laterally a few times in the bath; and when it has been in about a minute lengthwise, lift it out and put it in again sidewise. These steps may help you. 2. The lenses about which you enquire are by the maker you name.

Several letters and articles are compelled to stand over until our next.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to 32, PATERNOSTER-ROW.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 173.—*December* 27, 1861.

MY IMPRESSIONS OF PHOTOGRAPHY IN PARIS; AUTUMN, 1861.*

BY C. JABEZ HUGHES.

I have already stated my impression that English landscape photographers are more advanced than French ones. But I cannot resist the conviction that the French are superior to us in portraiture. I have been reluctant in coming to this conclusion, and have been trying to persuade myself that I am led away by the freshness and novelty of all things around me; but as I look on the collection of portraits in in the photographic exhibition, as well as those in the principal Boulevards, I feel compelled to acknowledge that those of our neighbours, compared with our own, surpass us.

Their *carte de visite* portraits possess greater softness and delicacy, are more uniformly sharp, having the head, hands, feet, and surrounding objects all equally in focus, and the figures are posed with greater ease and freedom. They also exhibit more taste and judgment in the use of accessories; the balustrade and column used more sparingly, and skilfully arranged drapery in the background is more frequently employed than among ourselves. Above all, I did not see in Paris any of those hideous abortions that, to the disgrace of all good taste, are now coming into vogue—profiled backgrounds. Painted backgrounds are not so much used there as here; and generally the getting up of their *cartes* seemed more quiet and in a better taste than ours. Consequently the figure is not lost in a mass of incongruous ornamental objects, but stands out as a portrait should do. The artists whose card pictures I most admired were Bingham, Mayer and Pierson, Ken, Pierre Petit, Pesme, Numa Blanc, Bilordeaux, and Mulnier.

Pierre Petit produces a class of pictures that is very admirable, heads about one-third life-size. They combine boldness with unusual softness and delicacy, and have none of that hard and unpleasant coarseness that ordinarily characterises the large-head photographs. They are quite untouched. Alophe, the successor of Legray, produces portraits yet more remarkable. These are heads and busts nearly life-size. They are said to be taken direct and untouched. If so, they are really wonderful, as, despite their noble size, they possess the vigour and softness of the best small pictures, and an entire absence of the repulsive grossness and distortion that usually accompany very large heads.

The pictures, however, most calculated to excite attention are those enlarged by Woodward's solar camera. Several of these are in the Exhibition, and one of the best, a head and bust of a lady, was contributed by Mayer and Pierson. This picture was sufficient to make a convert of anyone to the great merits of the instrument, for the modelling was so delicate, and the whole picture so sharp and vigorous. that I think prejudice alone could prevent any critic from acknowledging that all desirable qualities in a life-size photograph were combined in this one.

Count Aguado exhibits some of his charming pictures, enlarged by the same camera. Some rustic scenes, cattle ploughing, were uncommonly good. A portrait of himself, not quite life-size, was very soft and delicate.

Nothing shows more exactly than the solar camera the great disadvantages photographers in England labour under compared with those in France. With a clear atmosphere and almost constant sunshine, a photographer there may always use this instrument, but here its use is confined to the few summer months, when his time is entirely engrossed by his more direct occupation. If, therefore, Frenchmen beat us in the application of this instrument, some allowance must be made for the very inferior conditions under which we labour.

Though few Englishmen exhibit this year, it is pleasing to note that all that are sent are good pictures, and some of them are the best in the whole collection. What a perfect master of copying paintings is our compatriot Bingham! Whatever combination of blues, yellows, reds, or greens the artist may have used, he is sure to produce a charming copy of the painting. In his large collection of copies from celebrated pictures, there is so singular an uniformity of excellence that clearly proves that the photographic difficulties are not so great in copying from coloured surfaces as are supposed.

Vernon Heath contributes a frame of his exquisite pictures, as if to show what good landscapes should be. Mr. Russell Gordon of Chiswick, has some of the most exquisite pictures I have ever seen—views in Madeira. How is it we do not know more of this gentleman, for truly he is one of our very best photographers? While looking at his charming views I made a marginal note in my catalogue, that "they were examples of the very best English landscape photography, combining the sharpness and softness of Bedford, the delicacy of Heath, the atmosphere of Mudd, the sentiment of Robinson, and artistic feeling of Lyndon Smith," and I still feel that they merit this eulogium. I was proud to see such excellent work by a comparatively new name. I notice that this gentleman remarks that all his pictures were taken with wet collodion *heavily bromised*. Can this in any way account for the unusual softness and atmospheric feeling in these pictures? It is certainly confirmation for the advocates of bromine in collodion.

Mr. Annan of Glasgow exhibits three very nice Scotch scenes. It was very pleasant to stand in the *Champs Elysées*, to admire "the country of Rob Roy," the banks of Loch Lomond, and the old Clachan of Aberfoyl.

I looked in vain for art-photographs, in the sense that Rejlander and Robinson execute them. Neither in the shops nor the Exhibition did I see any. Can it be that this land of fogs is more favourable for the development of the poetic feeling? The most sentimental French landscape photographer, Silvy, has come to reside with us. Maxwell Lyte, who exhibits the finest French landscapes, is an Englishman; and Bingham, the man, *par excellence*, to translate French works of art into photography, is a Londoner. If, therefore, in the amicable contest of next year, when in the International Exhibition the best works of the best artists are seen side by side, if there our French brethren overpower us in one direction, I think we shall win laurels in another. If we cannot compete in the life-sized portraits produced by solar camera of Count Aguado, Mayer and Pierson, and Disderi—if the more directly taken portraits of Alophe, Petit, and Ken, are larger and more delicate than ours—if Bisson *frères* and Baldus show monuments and landscapes of larger surface—if even the *cartes* display more taste and finish (and on all these points, I, as an Englishman, hope my impressions are incorrect), we shall yet be able to point to our numerous landscape artists, as being far in advance of our French *confrères*. Beginning with Bedford, and ending with Wilson, the last and greatest of all, we shall show that we are years before them in capacity to do justice to the external charms of nature.

We shall also be able to show our successful efforts to get photography recognised as a Fine Art, allowing the works

* Continued from page 602.

of Robinson and Rejlander to prove that the camera is a perfectly legitimate vehicle of artistic expression.

With the capacity, therefore, to establish these points, we can willingly cede others, knowing that nothing so gracefully accompanies the capacity to teach as the willingness to learn.

I conclude my desultory impressions, then, with the hope, that when French and English photographers meet, they will manifest a disposition to do full justice to their several works, for on a fair comparison, I am convinced they have much to teach and much to learn from each other.

OPERATORS AND PROCESSES IN AMERICA.

Mr. Seeley, Editor of the *American Journal of Photography*, has not a very high opinion of American operators. Writing to our contemporary, the *British Journal*, he says—

"I have called upon some of our prominent photographers for preciso information as to their present methods of working. I have no difficulty in procuring the information desired, but I am somewhat restricted in the communication of it to the public:—1st. I am desired to omit any mention of names. Our photographers, like artisans generally, desire their neighbours and rivals to believe that there are profound mysteries: very few are willing to confess that they are no better off than others. Every ignorant man has his tremendous secret: it is only the most intelligent who have any modesty and feel that there is a narrow limit to their knowledge. I know no animal more piggishly obstinate and self-contented than your "artist" who throw away his lapstone only last week to become a photographer."

We hope Mr. Seeley's opinion of American photographers is to be understood in a "Pickwickian" sense, otherwise there could not be much reliance on the statement of their formulæ which he subjoins. We have reason to believe, however, from other sources of information, that he is correct. He says:—

"A large majority of our photographers manufacture their own collodion. The reason probably is in the fact that the ingredients of collodion are every where cheap and accessible. Alcohol, suitable for collodion of 95 per cent., is sold for fifty cents to one dollar per gallon, and ether for twenty-five to fifty cents per pound. The most ordinary proportions for ether and alcohol for collodion is equal parts. There are those who prefer an excess of one over the other, but tho old dictum of "five to three" is wholly abandoned. Every one here here uses a bromide in the collodion. In the early days of photography bromide of potassium was universally employed; now no one thinks of it, and only for the reason that it requires too much water to be introduced into the collodion in order to dissolve it. For a few years iodide and bromide of magnesium were great favourites, chiefly on account of their recommendation by one of our then high authorities, Mr. Moulton.

"For developer, the sulphate of iron is in universal use. Pyrogallic acid was laid on the shelf six years ago.

"The independent gold toning is adopted by all those who use albumenized paper.

"I present the following formulæ as the most relied upon:—

Collodion.

Ether	5 ounces
Alcohol	5 „
Gun-cotton	50 to 80 grains
Iodide of ammonium	50 „
Bromide of do.	20 „
Or with the above plain collodion—	
Iodide of potassium	2½ „
Do. of cadmium	4 „
Bromide of do.	2 „
Or,	
Iodido of potassium	5 „
Bromide of cadmium	2 „

"The silver bath—40 to 50 grains of nitrate of silver to the unce of water.

Developer.

Water	20 ounces
Sulphate of iron	2 „
Acetic acid	3 „
Alcohol	2 „

"In the remainder of the process thero is nothing worth mentioning, unless that the impression sems to be extending that it is unnecessary in printing to use over fifty grains of nitrate of silver to the ounce of water, for albumenized paper.

"As a strengthener for negatives sulphide of potassium may be found in every gallery."

EXCHANGES OF PHOTOGRAPHS.

BY COLEMAN SELLERS.

[It will interest many of our readers to learn from the following communications published in the *American Journal of Photography* that the system of exchanging photographs is beginning to be established amongst the photographers of the United States, although they do not seem as yet to have organized any regular club for the purpose. Members of the Photographic Exchange Club may derive some suggestions from the paper of Mr. Sellers.]

One of the greatest pleasures to be derived from the practice of amateur photography is in systematic exchanges. There are always plenty of friends ready to have us give them pictures which they innocently think cost us nothing. It is a pleasure so to give too; but a greater pleasure to enclose some pretty proofs to a photographic friend who will look at them with artist's eye, criticise their faults and praise their merits, and it is a pleasure too to tell him how they were done—under what circumstances of light, what make instrument, and so forth—and then in due course of time comes to us some return print from our friend, with some word of advice, and sometimes thanks for advice given.

Now, for my part, I do not like to mount my own prints, but I do enjoy mounting those sent to me; and it is with eagerness they are, when mounted, put into the instrument when passed, still wet with paste, around the home circle, and, while another is being mounted, listening to the exclamations of pleasure from wife, children, and friends. Stereographs too, are so easily sent by mail, unmounted, but they need some writing to explain each, hence comes the necessity of a printed label, which can be stuck on the back of the card and tell the story of the picture. That story is in two chapters, it must say what the picture represents as to locality, and so forth, and it should tell how it was made. This necessity has suggested to me a form of label which seems to work well in practice, and I here give it for the benefit of all interested—

MEMOIR.
JAMIN TUBES.
ARRANGEMENT.
OPENING.
COLLODION.
EXPOSURE.

No. Photographed by
COLEMAN SELLERS.

The blank space to the right explains itself as does also the memoir; but a word or two obout the memoir—this something to be remembered—it can be filled in:—*portrait* arrangement, *full* opening, *wet* collodion, *thirty seconds* exposure, *side light*, *dull day*, *strength with bichloride of mercury*.

Now I would earnestly recommend all who wish to exchange prints to have labels printed on some such plan as this—some way of telling how the negatives were made, and, better still, if some words were added as to how toned and fixed. It would be well too for those who can do so, and who have more time to be orderly than the writer has, to prepare a book; at the head of each page paste half a stereograph print, below it the memoir and number; and then as prints are sent away to those who will exchange, enter the name and date of each to whom a copy has been sent with memorandum as to tone and quality. This is the plan I propose to follow when, as I always say, I can get time to be neat.

THE PRINCIPLE OF THE DIORAMA APPLIED TO PHOTOGRAPHIC PICTURES.

(From the *Glasgow Daily Herald*.)

Within the last day or two we have had the pleasure of inspecting a highly interesting invention of our townsman Dr. Taylor, of the Andersonian University, by means of which the principle of the diorama has been applied for the first time to photographic pictures. Photography produces pictures admirably perfect in the form and proportions of their objects, and unapproachable in truthful accuracy by any other species of art. To give the charm of colour, and of changing light and shade, with the varied hues of morning, noonday, evening, or moonlight, along with the fidelity of the photograph, seemed to be all that was requisite in order greatly to increase the gratification derivable from the inspection of such pictures. The translucency of photographs on glass fits them in a greater degree than any other species of picture for taking on in a truthful manner changes of hue and shade by transmitted light; even the deepest shadows, from their semi-transparency, being capable of being affected in their hue by the general change of colour of the light. Dr. Taylor's principle and its application possess the merit of extreme simplicity; and, considering the sudden and rapid development of photographic art, it is somewhat astonishing that nobody had previously alighted upon this secret. The Doctor's problem was not merely to colour the photographic plate—not merely to produce successive transitions of colouring before the eye of the spectator, but to produce even the movement of clouds. This, we can say from what we have witnessed, has been successfully accomplished. The apparatus consists of an ordinary cosmoramic box, with a slide in the one side of it, for holding the picture, and with lenses on the opposite side, properly placed, through which the spectator looks at the picture. The pictures are carefully dimmed, or rendered slightly opaque in the light, to prevent the motion and forms of objects behind them from being too distinctly seen through them, and a little delicate and appropriate colour is painted on the opposite side of the glass. The chief modification and change of colour and shade are produced by the motion of a coloured surface placed behind the picture, and strongly illuminated by a row of gas burners, the light from which is kept from directly reaching the picture. This surface, on which the clouds and bands of graduated colour and shade are painted, is stretched round a light frame of wood, so as to give it a cylindrical or drum shape. The drum is about five feet in diameter, and is suspended by a cord from the roof. It is kept by the hand, or by means of some appropriate machinery, in a state of slow rotation, so as to bring the differently coloured and shaded portions successively opposite the pictures. The drum is placed at a distance of about nine inches from the picture; and the differences of distance between the lens and the drum contribute much to the beauty of the aërial effects. By this simple appliance, wonderful results are produced. Whatever perspective exists in a picture is brought out in a manner that the ordinary methods of painting need scarcely hope to equal, and every object bulks out from the picture with such completeness that one feels he could take a hold of it. It is scarcely to be doubted that this simple appliance, which could be easily fitted up, so as to be both portable and elegant, will yet be so mechanised, or arranged, as to become an agreeable means of enjoyment in many private families. It is right to say that Dr. Taylor has been ably and indefatigably seconded in his labours by Mr. Macnab, photographer, West Nile Street, who printed and prepared some of the plates, and in whose premises we had the pleasure of inspecting the apparatus. The actual measurement of some of the plates which we saw was 15 inches by 12; the magnified size, as viewed through the lens, was of course much greater.

Dr. Taylor suggests that the same mode of viewing stereoscopic pictures in glass, by means of a moving coloured background, might be followed, as it adds greatly to their effect. In this case a flat disc, turning on its centre, and laid flat on a table, seems to be the best form for use. The usual obscure glass used to cover the stereoscopic picture must be removed, and a transparent glass slightly dimmed, put in its place. Much of the beauty of the effect depends, as a matter of course, on the manner in which the bands of colour and shade are arranged on the disc.

Proceedings of Societies.

North London Photographic Society.

The usual monthly meeting of this Society was held on the evening of Wednesday, December 18th, in Myddelton Hall, Islington, G. Shadbolt Esq., in the chair.

The minutes of a preceding meeting having been read, Messrs. Noble and Francis were duly elected members of the Society.

The Secretary then read a paper on "the Original Fothergill Process," by Mr. Samuel Bourne, of Nottingham, in which the process, as originally published, was maintained to give results equal in excellence, and surpassing in certainty, most of the modifications and discoveries which have been promulgated since. The paper will apper in our next. Several large pictures, remarkably free from faults of manipulation, were contributed to the Society's portfolio by Mr. Bourne, as specimens of the process.

Mr. Hill observed, regarding the collodion most suitable for the Fothergill process, that he always found that sold for positives, namely, a thin bromo-iodized collodion, gave the best results.

The Secretary confirmed this remark, and referred to Perry's as a favourable example of the proper quality.

The Chairman observed that Mr. Hardwich had always recommended a thin collodion both for wet and dry processes.

Mr. Shave remarked that an especial advantage of such a collodion for dry plates was the fact that it developed so much better.

The Chairman thought that Mr. Bourne was in error in saying that no four drachm washing—by which he meant the limited washing, consisting of four drachms of water for stereoscopic plates, recommended by Mr. Keene—would allow plates to be kept a month. He (the Chairman) had, as he had before stated in that room, kept plates so washed for ten months and had still got clean pictures. These plates were 9½ by 7½ in. and were only washed in 4 drachms of water for that large size. He did not think keeping qualities depended upon the amount of water.

Mr. Hill thought that the chief thing insisted upon by Mr. Bourne was that a larger per centage of successful plates resulted from thorough washing,

The Secretary remarked that the observations on keeping referred to summer weather.

The Chairman said it was quite a mistake in reference to any weather. The plates he had referred to were kept from the 19th of June one year, to the May of the following year.

Mr. Shave thought that keeping qualities depended more upon the last washing water than the first.

Mr. G. Wharton Simpson observed that Mr. Bourne used a chloride in his albumen solution, which would tend more effectually to remove free nitrate of silver from the plates than a very copious washing.

The Chairman remarked that he attached great importance to a thorough final washing, and the application of a forcible stream to remove the albumen. In his own practice he used a flexible tube with a glass tap; the cistern containing the water was fifteen feet above, thus giving considerable force to the fall of water. The use of a tube in this way allowed the stream to be walked, if he might use the phrase, all over the plate.

Mr. Shave referred to the importance of covering the plate with an even wave of albumen. It was difficult to get the streams of albumen to join without causing a mark, if it were not poured in one even continuous wave at first.

Mr. Hill found great difference in samples of collodion for allowing the albumen to flow easily.

The Chairman said amongst the modifications of the

Fothergill process, that of Mr. Hannaford, or rather Mr. Barber's improvement upon Mr. Hannaford's method was worthy of attention.

Mr. Simpson said if he remembered correctly Mr. Barber proposed to add oxide of silver direct to the albumen solution, instead of forming it in the solution by means of nitrate of silver and ammonia.

After a conversation on the strength desirable for the albumen solution, in which it was agreed that the strength was comparatively immaterial, and a conversation on the specimens in which it was agreed that a slight amount of monotony, or absence of brilliancy, was due evidently to the lighting, and did not detract from the merits of the process, and the excellency of the manipulations, the subject dropped.

Mr. Hislop then expressed a wish to make a few observations regarding the discussion on his paper at a previous meeting, which he was unable to attend. In the first place, regarding the preliminary coating of albumen on his plates. Some gentlemen seemed to think that it would act upon his bath and discolour it. The argument might be strong and reasonable, but so far as his own experiments went, they tended to prove that no such action took place. His bath was prepared two years ago, and had had no doctoring of any kind since, except the addition of silver to keep up the strength, and sometimes the addition of acetic acid. In this bath some hundreds of plates had been excited, and fully nineteen-twentieths of these had been excited since it was his custom to coat with albumen, which he used, even for plates by the wet process, as he prepreferred to avoid the slightest risk of losing a good negative through the film leaving the glass. He had decanted a few ounces of his bath and brought in the bottle, which he now exhibited, and from which it would be seen the solution was perfectly bright and free from discolouration. As far as his own experience went, then, the use of the albumen did not spoil the bath. The next question was its effect on the picture. Some gentlemen seemed to think that much of the quality of the picture would be due to the presence of albumen, and some had even gone so far as to say that the collodion film might be removed and the picture left upon the albumen. He must confess he did not see how that was possible. As, however, he conceived experiment was better in such cases than either assertion or argument, he had prepared two plates, both with Ponting's collodion. One was upon albumenized glass, in his usual way, the other upon unprepared glass; they were both simply washed and dried as he had described in his paper. The pictures produced upon these plates he would now submit to the meeting, and ask the members to point out, if they could, which was on the albumenized plate, and which was on the unprepared glass. He was not prepared to assert that albumen was the best material wherewith to coat the glasses, but he had found no inconvenience from it. He believed its use was purely mechanical, and that it did not contribute in any way to the production of the picture. He was glad to see that Mr. Glover had recently suggested the trial of india-rubber for that purpose. For his own part he had met with a much larger measure of success, and obtained more good pictures, since he had used the preliminary coating than he had ever done before.

The Chairman thought Mr. Hislop was in error in one part of his remarks. No one had said anything about the effect of the albumen coating on the bath. He had himself said that the film of albumen itself would be acted on by the bath, through the coating of collodion, there was no doubt about that. The fact had been observed by numerous operators. Mr. Barnes, who was one of the first experimentalists in that direction, had found the picture so produced, to be on the substratum of albumen; and he (the Chairman) had himself actually removed the collodion and left the picture behind. In the picture shown, without a previous preparation of albumen, Mr. Hislop's position was much better illustrated.

Mr. Evershed asked if Mr. Hislop found the film of the finished picture harder for the previous coating of albumen.

Mr. Hislop had not noticed any difference in that respect.

Mr. Hughes said he had had some experience in working with plates which had received a preliminary coating of albumen. He used them for producing negatives by the wet process, and developing with iron. He could not say whether the same results would follow in dry plates, but it might be important to state briefly his own experience in the matter. He tried some years ago, when it was first proposed by the Rev. Mr. Laws; the object he aimed at was a sufficient amount of intensity by means of iron development without further intensifying, and it answered the purpose admirably, giving, with the ordinary bath, slightly acid, very fine negatives. Everything went all right until a few plates had been excited in the bath, and then the pictures began to be gradually covered with a foggy reduction, this continuing until they were hopelessly fogged in a very short time. He was compelled from this cause only, to give up the process, and at that time with great regret, as with a bromo-iodized collodion, and iron development it gave rich negatives combining the utmost sensitiveness, delicacy and vigour. He never observed that it discoloured the bath, but it unquestionably produced the results he had described. He had some of the negatives now, and had recently shown them to Mr. Simpson as specimens of the finest class of negatives, but for that unfortunate tendency.

Mr. Hislop could only say, that in his hands it had never produced those evils. He used the same bath and the same plates in photographing philosophical diagrams, which required the utmost clearness, some parts being bare glass.

Mr. Bingham asked if Mr. Hughes was careful to have his coating thoroughly dry?

Mr. Hughes said he was always careful to have the completest state of dessication.

Mr. Hislop said, possibly the very dilute character of the albumen solution might affect the question.

Mr. Hughes said very probably, indeed. He had used pure albumen.

The Chairman said, referring to the specimens, he could easily determine which had been produced on the albumen coated plate, as it was decidedly more vigorous than the other.

After some further consideration on the subject, in which Messrs. Simpson, Hughes, Hislop, and the Chairman took part,

Mr. Hughes remarked that Mr. Laws especially claimed for the preliminary albumen coating, that it gave increased sensitiveness.

Mr. Hislop found it gave decidedly more sensitiveness. On a ground glass, especially, he found longer exposure was necessary.

Mr. Evershed referred to a method recommended some time ago in the French journals, of rubbing a little pure albumen over the plate with a piece of cotton wool.

The Chairman thought that was a clumsy inefficient method of doing what Mr. Hislop did so easily, namely applying a very thin film of albumen to the glass.

Mr. Simpson asked Mr. Hislop for the precise details of his albumen preparation.

Mr. Hislop added one egg to eight ounces of water, and about half a drachm of glacial acetic acid to three ounces of this preparation. He floated it on to the plate like collodion.

Mr. S. Fry asked if Mr. Hislop had tried the effect of an edging of varnish round the plate?

Mr. Hislop had not found it sufficient to prevent films leaving the glass.

Mr. Fry had found it a perfect cure.

Mr. Hill then exhibited some stereograms, and the Chairman showed some specimens taken on slightly albumenized paper and waxed, to give them the finish of highly albumenized samples.

After the usual votes of thanks the proceedings terminated.

Correspondence.

FOREIGN SCIENCE.

[From our Special Correspondent.]

Paris, 24th December, 1861.

M. Faye, the astronomer, recently presented to the Academy of Sciences, a photograph representing a complete observation, obtained automatically, of the passage of the sun across the meridian. In displaying this first attempt at a new application of photography, M. Faye remarked that he had no hesitation in expressing his belief that the great future of photography lies in this direction. M. Le Verrier has renewed his promise to take into consideration the means presented by photography, so effectual and prompt, of obtaining delicate results, free from systematic and personal errors. The apparatus employed by M. Faye was constructed by M. Porro, and is so simple, and so nearly automatic, as to require only the superintendence of an ordinary workman.

Photography has also been made to lend new aid to the healing art. M. Czermack has availed himself of its resources, by applying it to laryngoscopy. He announces that he has completely succeeded in taking both single and stereoscopic pictures of the nasal and laryngical regions, illuminated by the mirrors of the laryngoscope. These photographs have been examined by the eminent anatomist, M. Flourens. To fix and exhibit in relief such organic cavities, which hitherto have scarcely been seen at all, is unquestionably a step in advance, for which surgery is deeply indebted to photography.

M. Migurski, of Odessa, has presented to our Photographic Society a set of proofs, obtained by the following method:—When he employs Woodward's Solar Camera, he uses a strongly sized paper. The silver bath is of the strength of 10 per cent., with the addition of 8 per cent. of crystallizable acetic acid, and 1 per cent. of carbonate of soda. The development is made with a saturated solution of gallic acid, to which is added ½ per cent. of citric acid. The exposure is very brief, from 2 to 5 seconds with a convergent lens of 12 inches in diameter. The proofs are well washed in the dark room before fixing, and toned with chloride of gold and sodium.

In another method, he employs an enlarging instrument, with parallel rays of light, and of 5 inches diameter. A negative obtained in the usual manner, upon a third or quarter plate, with an instrument of 3½ inches in diameter. When dry, it is copied in a frame upon a dry albumen plate. This copy must be very vigorous. The negative thus obtained may be enlarged to any desired dimensions. Generally a third or half the size of nature is preferable, upon a collodioned plate of 20 by 16 inches. For large negatives waxed paper is preferable. Develop with sulphate of iron, and strengthen with pyrogallic acid, to which ½ per cent. of citric acid is added. The exposure is often instantaneous, never longer than five seconds under favourable circumstances. An enlarged negative will serve for the reproduction of proofs by any of the methods generally in use.

It may justly be considered that the problem of the application of photography to topography has been solved by M. Chevalier in his invention of the *Photographic Plane Table*. This instrument gives at one and the same time, the station, point, and the azimuths of the various levels, so that the image serves immediately for the construction of a plan, without any geometrical construction whatever being required. I shall reserve the details of the operations of this instrument to another occasion.

You will, doubtless, remember, that a short time ago the Abbé Laborde published a communication on the employment of free iodine in the nitrate negative bath. He therein stated a fact quite at variance with chemical theories, viz., that the bath to which the iodine is added does not acquire acidity. This statement caused the greatest surprise among chemists, for it seemed incomprehensible that the iodine, in displacing silver, should not set some nitric acid free. M. Girard undertook to verify this statement, who finds the clue to the very natural error into which the learned Abbé has fallen in an interesting communication made by M. Adolphe Martin to the Paris Photographical Society. This chemist shows that most of the iodides of commerce, that of cadmium among others, contains a notable quantity of oxide, which can only be separated by dissolving the iodide in absolute alcohol. From this it appears probable that, by the employment of the impure iodides of commerce in collodion, the Abbé Laborde had dissolved in the nitrate bath not only some iodide, but also some oxide of silver, the quantity of which may be, perhaps, much more considerable when iodide of ammonium is taken, which produces in the silver bath some nitrate of ammonium, the dissolving properties of which, in relation to oxide of silver, are well known. Thus it happens that in subsequently adding free iodine to such a bath, the latter will carry its action, not upon the nitrate, but upon the free oxide, so that there will be formed, at the expense of this base, some iodide of silver, and this is ameliorated in becoming really more neutral without acidity manifesting itself. But when M. Gerard to a nitrate bath of the strength of 7 per cent. saturated with pure iodide of silver, prepared by means of iodide of cadmium, purified in absolute alcohol, it was sufficient to add to this bath a very feeble trace of free iodine for it to become immediately acid to test-paper.

M. Anthony Thoret communicates the result of his attempts to act upon the Abbé Laborde's recommendation as follows:—he added 6 grammes of iodine to 200 c. c. of nitrate bath. Two hours afterwards the iodine was covered with iodide of silver. Blue litmus paper immersed in the bath turned red instantly, as if by the action of a strong acid. Thinking that the bath might not have been completely saturated with iodine, another, 100 c. c. well saturated, was taken, and 3 grammes of iodine added, but with the same result. Lastly, he took a third bath, with the excess of iodide left in suspension: the same result attended the addition of the iodine.

In the presence of so large a quantity of free acid it was useless to try a plate, but the whole of the quantity experimented upon were mixed together, and the nitric acid saturated with oxide of silver formed in the bath itself by the addition to it of lime water. It appeared to result, that in the course of two hours, of the 12 grammes of iodine added, 89 centigrammes were combined with 77 centigrammes of silver to form 1·66 grammes of iodide, by liberating 39 centigrammes of nitric acid saturated subsequently by 2 decigrammes of lime. If the reaction had continued with the same energy for 27 hours, all the iodine would have become transformed into iodide.

ON MOUNTING PHOTOGRAPHS.

Sir,—This necessary operation having long been a source of annoyance and trouble to me, I was glad to see the topic discussed in so useful a manner at the meeting of the South London Society, reported in the News of November 22nd. One important point was apparently unnoticed, viz., the quality of the cardboard mount with respect to its power of resisting cockling. I have found that different makes of cardboard possess very marked differences when treated in precisely the same way. One batch of stereo mounts procured by me last summer is so bad, that I find it impossible to mount prints on them (even when dried under slight pressure), without finding the mount warped to some extent at the end of the process; and as this fault does not occur with mounts procured from another source, I feel justified in blaming the cardboard, and think that the subject is worthy of the consideration of amateurs, and the dealers who supply them with photographic desiderata.

I may add that I invariably use fresh starch, mixed as thick as will admit of its being spread with a stiff brush.

I am, sir, yours very truly,
Rho Delta.

Sir,—The discussion reported in a recent number of the Photographic News, on the subject of mounting photographic prints, is one of great importance to every artist and amateur of the art, and too much attention cannot be called to the subject. I have frequently seen the appearance of the finest prints, as such, completely spoiled by bad mounting, even in some of our crack exhibitions. It may be, as yet, a moot-point as to what adhesive substance is the best for the purpose; it is not, however, I am convinced, on the other hand, difficult to name from actual experience several that should be avoided. Gum, for instance, gelatine, common paste, or starch, are never used, I believe, by professional mounters, who, I daresay, have good reason for eschewing them; and amateurs would do well to follow

their example. The substances most frequently used, are, I am informed by one of our principal photographic mounters, dextrine and glue, according to the size of the photograph, and the kind of paper or cardboard on which the print is mounted. Indeed, the only difficulty in the whole matter, as far as the mounting is concerned, rests with the mount itself. I have always found a difficulty in this respect myself, except when I have used very thick five or six-sheet cardboard, by which the cost of the mounting is greatly increased, and the artistic effect, as compared with "plate" paper, considerably decreased. I have lately had a number of large views mounted by a firm in Paternoster Row, in a very excellent manner, for the Exhibition of 1862 on a paper similar to that used for printing first class engravings on, and with a tint, in imitation of india paper, like that referred to in the Photographic News. There is no appearance of "cockling," and the prints are very highly glazed. I understand that the adhesive substance used in this case is some kind of dextrine, specially prepared for photographic mounting. If you will allow me, I will just hint that the gentlemen named would confer a great boon on photographers in general, and especially on those resident in the country, if they would explain their method of manipulation, or, at all events, bring the substance they use into the market commercially. As far as my prints are concerned, I have no hesitation in saying that the mode in which they have been treated far exceeds my expectation. They are "thrown up," as it were, in a wonderful manner; a result I attribute to the substance with which they have been mounted. You will excuse a photographer's fondness for the offspring of his labours, and pardon my going so fully into the subject. I do not write to you with a view to puffing any particular house, but simply to record my experience, for the benefit of others, as one of the earliest amateur photographers, on a matter of such great importance, feeling convinced as I do, that no picture can look its best unless it is well mounted. I need say nothing of *squaring*; the artistic eye can scarcely be more offended than by a picture cut or mounted *on the squint*; nor on the subject of *margin*—that is a question of taste, which experience will soon reduce to a rule. The French are very particular, and very successful, in both these respects, as will probably be seen at Kensington next year. I hope that some, at least, of their *confrères* in the domain of art will not be behind them in this apparently trifling, yet really very important, point.—I am sir, yours respectfully,
Cupar Robertson.

Blackheath, 10th December, 1861.

SIZE *versus* QUALITY.

Sir,—On behalf of my professional brethren and myself, I deem it right to offer a few words on the article in a recent News, "Photography and its Students," by Mr. Samuel Fry.

It cannot be denied that there *is something wanting* amongst the amateur and professional photographers of Great Britain as to the production of large-sized pictures, but in the majority of cases, it will be found that much as amateurs admire and desire to produce large pictures, they have in very many cases, neither the money to expend in the necessary purchase of apparatus, or the time to give to their production, even if they had it. Some few that I know have the means of producing pictures up to 22 by 17. But the majority inform me that "it's all very well now and then to take these pictures, but it's a great bore." With professionals, on the other hand, it is something similar. We as a nation are not fond of change, and we prefer sticking to what is really good rather than attempting what a "discriminating public" would unhesitatingly consider *bad*.

On the Continent and in America, it must be borne in mind that wages and materials, rent, food, &c., are considerably cheaper than with us, and in some countries government lends its aid to the photographer.

With the bulk of our professionals, both in town and country, the pourtraying of the human face divine is more lucrative than all the large landscapes and buildings would be, and we very naturally keep to that which enables us to live; and I think it will be found that the proportion of professional photographers in landscape and portraiture (as far as England is concerned) is as one to five. Of dry plate photography I know but little—enough for my own purposes—as in its present stage very little reliance can be placed on any one particular process. I say, nothing like "wet collodion" for certainty. At the same time I would, in common with my professional brother, Mr. Samuel Fry, urge on all intending exhibitors to strain their utmost to produce works (whether they be great or small) worthy of Great Britain and its amateur and professional photographers.—I am, sir, yours &c.,
W. H. Warner.

Ross.

PERMANENT PRINTS, FIXING BEFORE TONING.

Sir,—In the News of the 6th inst., I see there is reference made, by a correspondent, to a French process of "fixing before toning," and also a note by yourself to the effect that the process is both "tedious and unsatisfactory" so far as albumenized paper is concerned. But as you spoke rather from uncertain data, I thought that a few observations from one who has had considerable experience in the process might be of some service to your readers. One thing I am quite certain of, that you can invariably get pure whites, transparent shadows of a fine rich brown, or a deep purple tone, without fear of failure. And that the prints are more permanent than those toned by any other processes that I have tried. Enclosed is a print on albumenized paper, done three years ago, and it has lost none of its brilliancy, and that is more than I can say of some of my prints toned by the alkaline toning processes. You must not suppose that it is through the varnish on the print that it retains its brilliancy, as a spoiled print (spoiled through uneven pressure) done at the same time will speak the contrary. If you think the process of any service, I shall be happy to communicate the same to your readers.—Yours respectfully,
Thos. Tedrake.

Appledore, Devon, Dec. 17th. 1861.

[We shall have pleasure in receiving details of our correspondent's experience in this matter.—Ed.]

PHOTOGRAPHIC CARICATURES AT ROME.

(From *Punch*.)

In a letter from Rome it is stated that—

"The official journal of yesterday contains an edict from the Cardinal Vicar announcing that no one will be allowed to exercise the art of photography without authorization from the Rev. Master of the Sacred Palace, from the Cardinal Vicar, and from the police, under penalty of 50 dollars fine. Amateur photographers are liable to the same regulation."

A maternal government imposes this restriction on the personal liberty of its subjects, because some of them abuse the photographic art. Provision for the punishment of offenders in that kind, one would think, would suffice to meet the case; and their correction has been tolerably well provided for by the arrangements thus specified:—

"The producers and distributors of indecent photographic plates are to lose their instruments, to be fined 100 dollars, and to be sent to the galleys for a year; the same penalty to be inflicted on the models who may have served for such productions."

Serve them right. But what cause has the Roman public to thank the papal Government for giving it the benefit of an improvement on Lord Campbell's Act? We further read that—

"It is stated that this edict . . . was absolutely called for by the recent clandestine publication of some very scandalous photographic representations in which the heads of the Pope, Cardinal Antonelli, the Queen of Naples, and other persons of high rank, were placed on the bodies of other individuals in such a skilful manner as to deceive any spectator, and with such a disregard, not only to delicacy, but also to decency, as fully justifies the measures adopted by the Cardinal Vicar."

Would his Eminence have interfered with the licentious photographers if they had placed the heads of Garibaldi, Victor-Emanuel, the Emperor of the French, Lord Palmerston, John Bull, and *Mr. Punch*, in the same vile relations as those in which they put the upper storeys of Antonelli, the Queen of Naples, and his Holiness, or in any relations however vile? And if the head of the Pope were put on the body of a figure in pontificals blessing a Neapolitan brigand, that of the Queen of Naples on the shoulders of *Moll Flagon*, and Antonelli's on those of *Fra Diavolo*, would not the Cardinal Vicar consider the photographs so composed as exhibiting a grievous disregard to decency as well as delicacy? It is no doubt sacrilege as well as high treason at Rome anyhow to take off the head of the Church. What a wonder the Sun lends himself to such an enormity! Cannot Pius excommunicate Phœbus?

Miscellaneous.

Photographic Aids to Physiognomy.—It is equally true that with such portraits and engravings of portraits as we have had, it has been utterly impossible to get beyond the nebulous science of a Lavater. We required the photograph. Certainly it looks a hard thing to say that the great portrait-painters are not to be trusted. Is it to be supposed that these masters did not know their business, and have failed to give us correct likenesses of the persons who sat to them? It must be remembered that to give a general likeness is one of the easiest strokes of art. With half-a-dozen lines the image is complete, as anyone may see in the million wood-engravings of the day; while, at the same time it would be difficult to gather from these rough sketches, where two dots go for the eyes and a scratch for the mouth, what is the precise anatomy of any one feature. So, while we can accept as in the main truthful, the portraits that have come down to us, it is impossible to place perfect reliance on any particular lineament. Take the upper lip, for example. This is perhaps the feature of the face which not only the portrait-painters, but likewise all the copiers of the human form, have most trifled with. We can often accept the lower lip that they give, but the upper is a myth. Then of this upper lip, we can sometimes rest content with the corners, the artist looking chiefly to these for the expression, but of the middle part we can never be certain, except in the knowledge that nineteen times out of twenty it is false. There is a form of this part somewhat like a Cupid's bow, which is considered the most beautiful, and which the painters are always repeating. The centre of its upper line comes down to a sharp point, and the centre of its under lines falls into a point rather less sharp, and forming a little ball or drop that sometimes delicately clasps the lower lip, sometimes (especially in Raffaelle's heads) hangs loose above it, and parted from it. From these two points the lines sweep away on either side in two pairs of ogee curves, which are now and then caricatured (very frequently by Vandyke) in the undulations of the moustache above. Such is Raffaelle's favourite lip: he hardly ever has a face without it. One would fancy that all the people of Vandyke's acquaintance had it. Kneller is great in it; so is Fuseli. Sir Thomas Lawrence gives it with a vengeance to all his sitters—curling the curves, and making the little drop in the centre almost drip. The painters are never satisfied without it, and give it to all their heads alike—to Cortes as well as to Cervantes, to Descartes as well as to Shakespeare, to Arkwright not less than to Schiller and Goethe. What the painters do badly, the engravers do worse; and so this lovely lip is rendered vulgar and meaningless. Belonging to a few, and that few a defined class, it is represented as the common property of all. Nothing short of the photograph can correct this uncertainty, and make the physiognomist feel that he is on sure ground. The photographs produced by such men as Mayall, Dickenson, Silvy, and Watkin leave little to be desired. Nothing more truthful, and nothing cheaper. A collection of good portraits is now within everybody's means; and everybody is making a collection. Let us hope that something will one day come of these numerous collections.—*Cornhill Magazine.*

Photography on Phosphorus.—Dr. Draper has just made known a curious photographic action which light possesses upon phosphorus. He found that ordinary yellow phosphorus on exposure to light became converted into the allotropic red modification of that element. He, therefore, formed some into a thin sheet by melting it between two plates of glass. On this surface he succeeded in photographing the fixed lines of the spectrum and in taking on it prints from negatives. Some of the prints have been preserved in the dark for five or six years. As the yellow modification of phosphorus is readily soluble in several media, whilst the red variety is almost insoluble, these prints could be readily fixed by pouring ether or bisulphide of carbon over them; the unimpressed parts would thus be readily dissolved away. On account of the great inflammability of phosphorus these pictures can only be looked upon as chemical curiosities; they are, notwithstanding, of great interest.

A Cheap Prism.—A correspondent of the *Scientific American* says:—Having read an interesting account of the spectroscope, I set my wits to work to construct one for my own amusement; not having the chandelier ornaments or any solid pieces of glass to construct the prisms of, I took a very clear thin pane of window glass, cut out two pieces to suit my taste, cut a thin back and bottom for the third side, fastened with thin strips and set the glass with putty, making a very thin prism with open top in which to turn some clean water when I wished to use it. The prism would have to sit on its end, instead of lying longitudinally, which I suppose makes no difference in the reflection. I think it has some advantages over the solid prisms. Defects in the material used do not show so plainly, the cost is slight even for a large one, and they might be constructed tight like a spirit level, and used in any position. Most people have skill enough and material handy for the construction. [If the correspondent will fill his prism with the bisulphide of carbon he will have the prism used by Bunsen and Kirchoff in their apparatus. Water, however, makes a good prism.—Ed.]

Talk in the Studio.

Booking a Customer.—Messrs. Cutts and Longstick, who have suffered much from the difficulty attending the identification of "clients" on their return from a lengthened tour, resort to the accompanying device. Whilst the captain is being measured by the foreman, the junior partner, behind the screen, adjusts the camera for his photograph.—*Punch.*

The Sale at M. Silvy's.—An auction sale of photographic effects is somewhat a novelty; the announcement of one did not, however, attract many known photographers, and the few we observed present seemed to have been drawn rather by the desire to see the premises of a gentleman who—notwithstanding the inquiry of the President of the Photographic Society, "Who is Silvy?"—has acquired one of the most extensive photographic connections throughout the country, and a reputation European in its extent. A royal album he showed us recently contained portraits he had taken of members of almost every royal family on the Continent. The large premises behind the house present the aspect at this moment rather of a builder's yard than anything else, in consequence of extensive alterations and increased appliances for the coming year. The day before the sale about a thousand negatives were in course of printing amidst this chaos. The effects offered for sale were chiefly the residue of apparatus, specimens, &c., which M. Silvy had received from Caldesi and Montecchi, in purchasing the business of them two or three years ago. It was somewhat amusing to hear the auctioneer, in offering the goods, commending them as of "tried quality," forgetting to add, however, and "rejected." Some of the articles sold were doubtless of good quality, and many were of that character which *will*, somehow or other, accumulate in every studio of any standing, cumbering it without adding to its efficiency. Many of the articles sold for singularly small prices, and many others for sums much higher, we apprehend, than their original cost. An 8-inch French single lens, for instance, sold for £30, a sum which struck us as excessively high for an unnamed, untried, unguaranteed lens, without even its focal length stated. Some excellently executed coloured specimens sold for much less than the value of the frames. The proceeds were, we believe, in round numbers, about £180.

Turner's "Liber Studiorum."—The *Athenæum* says:—"The series of photographs from Turner's *Liber Studiorum*, published by Messrs. Cundall and Downes, would be more valuable if extended to embrace the whole number of seventy-one drawings made by the artist towards the one hundred of his original intention. Many more of these works are, we understand, in possession of the Trustees of the National Gallery than those already reproduced from the series at South Kensington. Is there any reason why the photographed *Liber* should not be completed for the benefit of the public and artists? Renewed examination of the series has strengthened our conviction that these marvellous works should be disseminated in the widest possible range. The publishers deserve credit for what they have done towards this end; and, aided by public authority, we hope they may complete the series in question.

Photographic Exchange Club.—A correspondent says: "Regarding the "Photographic Exchange Club," I think it would be an excellent plan to write along with the other information, the kind of paper upon which the view is printed and the albumenizer of it.

The Gorilla Lecturing on Mr. Spurgeon.—The London Stereoscopic Company have just issued a clever little pictorial *jeu d' esprit* in the form of an album-photograph, representing an excited gorilla lecturing to an audience of still more excited gorillas The subject of his lecture is a dissenting preacher, who it is well-known has acquired a certain kind of celebrity by lecturing on apes and vermin. A sculptured bust of this gentlemen is placed upon the table before the oratorical gorilla who rests one hand on the head, whilst the other is extended in characteristic fashion. The date of the scene is supposed to be A.D. 5862. Behind the lecturer is "an ancient engraving: date, 1862," representing a well-known portrait of the preacher. The origin of this quizzical sketch is indicated in a quotation from the speech of Mr. Layard, in which he refers to the possibility in "after ages of having a gorilla lecturing on Mr. Spurgeon." In the attempts to produce something funny the art has often been prostituted to purposes with which, as we have before declared, we have no sympathy. We think in this case, however, there is "fair game" in the circumstances. The photographic effect, however managed, is very clever.

To Correspondents.

*** To our Readers.—The next number of the Photographic News will contain the Index to the Fifth Volume. It will consist of four extra pages, for which no additional charge will be made. Arrangements are in progress for articles on a variety of interesting subjects, which have hitherto received very little attention. Amongst others we may mention a series of articles critical, descriptive, and suggestive, on the whole of the apparatus at present used in photography, considering how far the means in existence are best adapted to the ends in view, or how they be made so.

Cass.—The mottled mealy effect of which you complain is, unfortunately, very common with some samples of albumenized paper, when the alkaline gold toning bath is used. The best remedy is slow toning. The stronger the gold toning bath and the more rapid the toning, the greater the danger of mealliness. Try the toning bath with the acetate of soda which we have given several times lately, and which is also given in the Photographic News Almanac. Many operators have, by the use of this bath, succeeded in entirely getting rid of this mottled effect.

N.—The "Sablier Compteur" arrived safe, and we are much pleased with it. Thank you for the courteous attention. We will ascertain if some manufacturer will introduce them. For general photographic purposes, perhaps it would be well to have them graduated to 60 seconds. We will introduce the matter to our readers shortly.

W. Bartholomew.—We are obliged by your communication which shall appear in our next. We will, as early as our engagements permit, try the processes. We presume the rapid plates with which you recently favoured us, were by the last described process. We hope to try them soon.

Annesley Free.—It is always desirable to remove the free nitrate of silver from the print previous to immersion in the toning bath. We give it two or three changes of water, allowing it to remain five minutes in each.

Charles West.—Three thicknesses of your yellow glass will render your dark room much too obscure for convenient working, and it is doubtful whether, in full sunlight, they will entirely resist the actinic rays. One thickness allows all the green rays to pass, and a small portion of the blue. One thickness of a suitable glass would be much more efficient than three this. We cannot give you any certain information as to where a certainly good sample can be had, for it frequently happens that a perfectly non-actinic quality is kept one day by a firm, and on the morrow, a perfectly worthless sample is supplied as the same article. All we can do is to recommend you to ask for the silver flashed glass. We are obliged by the expressions of your good opinion.

Cornish Chough.—We have, at intervals during the last few months, published a series of articles on the best condition of collodions, bath, developer, &c, for iron negatives. The Photographic News Almanac just issued, contains some carefully considered articles on the same subject. For wet collodion and iron development we prefer a bath very slightly acid with nitric acid; collodion made from pyroxyline obtained at a high temperature with weak acids; ether and alcohol in equal proportions, or an excess of the latter; iodized with a mixture of cadmium and sodium and about half-a-grain of bromide to four of iodide. For details see our Almanac.

Leicester.—At the present time, we believe, *Cartes de Visite* are the most remunerative class of portraits, produced by professional photographers. They are not the most profitable, *per se*, perhaps, as there is a good deal of printing, mounting, &c., for the money; but they are generally ordered in quantities. Moreover, if the work be well done, each one sent out is a recommendation, and almost certainly brings fresh custom. Thus, a sitter orders a dozen copies; in giving these to his friends, he places each one, to a certain extent, under the obligation of giving a portrait in return; and thus it happens that every portrait taken becomes, as it were, the nucleus of a fresh order. One whole-plate portrait at a guinea might be more profitable to the artist than a dozen cards at the same price; but for every single customer for the first style he may have a dozen customers for the last. We know many artists who are sending out from one to two thousand cards weekly. The tide may change in time; but there is no symptom of it at present.

Sigma.—In replenishing a bath, all you have to do is to add the amount of silver and water, which on examination you find are deficient. For instance, you wish to make your bath, which you state now contains 600 grs. of silver in 18 oz. of water, up to its original strength of 1200 grs. in 20 oz. of water. Simply add 2 oz. of water and 600 grs. of silver; and so on with other solutions. 2. The black powder in your negative bath is probably organic matter, which was present either in the water or silver, which has now become reduced by the action of light. It simply requires to be filtered out. 3. Almost all collodion makers issue bromo-iodized collodions. Thomas, Burfield and Rouch, Hughes, Horne & Thornthwaite, Keene, Perry, and many others. We believe Pontings's contains a bromide; but the maker gives no account of its preparation. 4. The germ may be removed from the white of an egg by lifting it away with a fork.

Ein Frager.—Photographic transparencies may be exhibited in the magic lantern just in the same way as the usual lantern slides. The transparencies are produced from a negative, either by means of super-position or camera printing. Several articles on the subject have appeared in the present volume, as the index will show. The article on Copying and Enlarging, in the Photographic News Almanac, describes the mode of proceeding in camera printing.

T. G. S.—It is probably the fault of your camera or dark slide. Focus some object carefully, and then remove the ground glass, and put the dark slide with the back open in its place, with a piece of greyed glass in the position which would be occupied by the plate. If the image be not sharp on the greyed glass, the dark slide is in fault and will require adjusting, so as to bring the plate into exactly the same plane as that occupied by the ground glass focussing screen.

X. Q.—In all our statements of formulæ where "acetic acid" without any qualifying term, is mentioned, glacial acetic acid is meant. In articles extracted from American or other journals we cannot be so certain as to what is meant; but we always receive the term as meaning glacial acid.

Amateur in Positives.—We have never used the American Niello paper, but we presume the manipulation will be the same as with mica. Of course the same chemicals as usual will be used.

T. R. H.—If you made ten grains of chloride of gold into a bath, and used the whole at once to tone your prints, you did a very unnecessary and foolish thing. One grain of gold is sufficient to tone thirty or forty album portraits, and that is quite as many as, or more than you should have in at one time. It is easy to replenish the bath with unused solution when a few dozen prints are toned, and the operation begins to be tardy. By following such a course you could never risk the waste of much toning bath at a time. A variety of causes will produce precipitation of the gold. Immersion of the prints without having removed the free nitrate of silver, or contact with fingers which have recently touched the hypo will do it, and various other causes. Do not throw the bath away, however; if it refuse to tone, precipitate any remaining gold by means of protosulphate of iron. The gold will be thrown down as a dark powder, which may, when sufficient of such residues are collected, be made into chloride of gold by solution in aqua-regia in the usual manner. 2. Glass positives are vignetted in two or three ways. The best is by placing a screen with a vandyked aperture of the desired shape, a few inches in front of the lens so as to be completely out of focus. If the figure is to graduate into a light ground, the screen must be painted a light colour: if into a dark ground, the screen must be dark. In each case the background screen should be a similar tint to the vignetting screen.

Several Correspondents in our next.

INDEX.
